"The care of the human mind is the most noble branch of medicine."—GROTIUS

BALTIMORE

1937–1938

The Lord Baltimore Press
BALTIMORE, MD. U. S. A.

CONTENTS OF VOLUME 94

JULY, 1937.

1. PRESIDENTIAL ADDRESS. PERSPECTIVES IN PSYCHIATRY. *C. Macfie Campbell* 1
2. C. MACFIE CAMPBELL, M. A., B. Sc., M. D. *William L. Russell*..... 15
3. A NOTE ON THE URINARY PHOSPHATE OF NIGHT URINE IN MENTAL DISEASE. *Walter Michael Bachinski and James Jamieson Rae*.... 19
4. THE EFFECT OF BENZEDRINE SULPHATE ON CERTAIN ABNORMAL MENTAL STATES. *Purcell G. Schube, M. C. McManamy, C. E. Trapp, and A. Myerson*..... 27
5. DEFINITION OF CHILDHOOD IN PSYCHIATRIC LITERATURE. *Charles Bradley* 33
6. SIX YEARS EXPERIENCE WITH NARCOSIS THERAPY IN PSYCHIATRY. *Harold D. Palmer and Francis J. Braceland*..... 37
7. HYPERTHYROIDISM AND PERSONALITY. *Warren T. Brown and Edwin F. Gildea.* 59
8. THE SIGNIFICANCE OF SPECIAL READING DISABILITY IN MENTALLY HANDICAPPED PROBLEM CHILDREN. *Thorlief G. Hegge*..... 77
9. SYMPOSIUM ON THERAPY INCLUDING HYPOGLYCEMIA:
   - THE PSYCHIATRIC MANIFESTATIONS OF HYPOGLYCEMIA. *Edwin J. Kepler and Frederick P. Moersch*..... 89
   - THE METHODICAL USE OF HYPOGLYCEMIA IN THE TREATMENT OF PSYCHOSES. *Manfred Sakel*..... 111
   - REPORT OF THE HYPOGLYCEMIC TREATMENT IN NEW YORK STATE HOSPITALS. *John R. Ross*..... 131
   - EXPERIENCE WITH THE HYPOGLYCEMIC TREATMENT OF SCHIZOPHRENIA. *Solomon Katzenelbogen, Herbert Harms and Dean A. Clark* 135
   - FURTHER EXPERIENCES AT BELLEVUE HOSPITAL WITH THE HYPOGLYCEMIC INSULIN TREATMENT OF SCHIZOPHRENIA. *Joseph Wortis, Karl M. Bowman, Leo L. Orenstein and Irving J. Rosenbaum* 153
   - EXPERIENCES WITH THE HYPOGLYCEMIC SHOCK TREATMENT OF SCHIZOPHRENIA. *G. Alexander Young, Richard H. Young and L. Roucek* 159
   - THE EFFECT OF THE HYPOGLYCEMIC THERAPY ON THE PSYCHOTIC PROCESS. *Bernard Glueck*..... 171
   - THE PROBLEM OF INSULIN SHOCK. *Henry J. John*..... 175
   - THE ENCEPHALOGRAM OF SCHIZOPHRENICS DURING INSULIN TREATMENTS. *Hudson Hoagland, D. Ewen Cameron and Morton A. Rubin*..... 183

UNIV. OF MICH.

PERSPECTIVES IN PSYCHIATRY.*

By C. MACFIE CAMPBELL, M. D., Boston, Mass.

In all human affairs the point of view from which they are regarded makes a considerable difference. So in matters psychiatric, and in regard to The American Psychiatric Association and its annual meeting. I find the perspective from the presidential chair different from that of the care-free member, and my remarks shall deal with this new perspective.

This is the opening session of our annual meeting. The annual meeting is more than a social event, it is an intellectual feast; the menu is comprehensive, almost bewildering, a presidential address is supplied as a somewhat dubious cocktail. In the simpler times of the founders of the Association the members ate steadily through the menu, but now the atmosphere is more that of the cafeteria. One picks and chooses according to his individual taste; while some select a highly specialized fare, it is hoped that the average member after the meeting will look back on a well-balanced, palatable and digestible meal.

The program of the annual meeting, however, is not to be considered a mere collection of unrelated papers presenting the results of independent workers in their various workshops. Each worker is dependent on the thought of his time, utilizes formulations suggested by others, is stimulated by the special interest of his colleagues. The papers form part of an integrated whole. The program represents a cross-section of contemporary psychiatry. Within the general field of psychiatry there are shifting foci of special activity, foci which are not dissociated from the general activity but which exert a marked influence over the whole field. Brain potentials, detailed anatomical changes, the physical and chemical variations of blood and cerebrospinal fluid, details of the chemical equilibrium of the body, the nature of the instinctive urges, the organization of the personality, its various patterns of reaction,

* Presidential address delivered at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

its transitory disorders, its permanent distortions, the complicated play of inter-personal relations in home and school and job, the various physical, chemical, personal and social resources available for treatment—such is the diet provided by this year's program, such are the challenges to your interest and your critical judgment.

Different problems and different methods have had a varying degree of attention at different periods; at one time the practical problems of hospital administration were in the foreground, at another the varying clinical manifestations, then again the structural substratum or the nature of the physiological disturbances. Chemical studies and the experimental method have somewhat put in the shade studies by means of anatomo-clinical correlation.

The program is a stimulus to the worker in a special field, it is a challenge to the less specialized worker who aims to coordinate the specialized results and utilize them in the setting of his more immediate clinical tasks. The annual meeting offers a demonstration to the general medical profession of the present status of an important medical specialty. To the community the Association at its annual meeting offers an account of its stewardship.

At a time when the relations of the medical profession to the general needs and resources of the community are being scrutinized, each one of us must consider seriously the relations of this representative body of our specialty to the important issues of the individual life and of community organization. As he watches current events the psychiatrist sees many personal tragedies, the underlying factors of which seem clear to him, as they form the stuff of his daily work. He sees strained and antagonistic relations between parents and children, distorting and embittering the lives of both. He sees troubled marital situations where a somewhat different attitude and a broader grasp of human nature might transform the lives of both partners. In the school he studies the interplay between personality of pupil and that of teacher, and sees in this interplay the same fundamental forces of human nature which he studies in his patients. In various group movements connected with religious beliefs, social attitudes, economic dogmas or political formulæ he sees the underlying rôle of instinctive and primitive urges and attitudes, while little reference is made to them in official utterances and discussions. In labor conflicts where the discussion is officially about hours or wages or forms of organization, the urge

for power in the protagonists of the two sides, the results of early conditioning, of unresolved conflicts, of present tensions, may have much to do with the intransigent attitude which foments trouble, neglects friendly approaches, postpones reasonable settlement; while the response of the less articulate members of the group can only be understood if we know the actual conditions of their life and are sensitive to the needs of human nature and the results of its frustrations. Ruthless exploitation, anti-social behavior, stubborn conservatism and crude radicalism, phantastic beliefs, ill-balanced enthusiasms, these are merely manifestations of the human spirit working according to its definite laws under the special conditions of the individual and social life.

It is these laws which the psychiatrist is bound to search out, and the nature of his task offers him unique opportunities for their investigation. No other situation is so favorable as that offered by the consulting room, where with all irrelevant social conventions removed it is possible to lay bare the movements of the human soul.

The insight of the psychiatrist, imperfect as it is, into the laws of human behavior is of fundamental importance for meeting crucial problems which concern the individual life and the social structure. The psychiatrist has a natural desire to promote the social utilization of the psychiatric knowledge that is already available.

In the complicated field of human relations there is no single feature so startling as the mass destruction of one's fellow creatures because of conflicts as to beliefs or material possessions. Yet war is a commonplace; it is accepted by some as if it were an inevitable condition of human existence on this planet, as if human nature had some ineradicable tendency bound to express itself in recurrent outbursts of mutual destruction. With this fatalistic attitude all the skill and all the intellectual processes of man may be made subservient to the accomplishment of this destructive task.

It was therefore refreshing to hear a different note sounded by a group of men whose life task was to study the underlying urges of human nature, the results of their frustrations, the lines along which one might strive to reach a wholesome solution for the problems of the individual and the social group. This group of men started from no dogma, could not be accused of unfamiliarity with scientific method, their life had accustomed them to the exercise of critical judgment. They were familiar with the principles of the

physical and the biological sciences; they were no group of visionaries. I refer to the appeal sent out in 1935 to all the statesmen of the world by a group of 340 psychiatrists and psychologists from 27 countries. This appeal was formulated by the Committee for War Prophylaxis of the Netherlands Medical Association. This appeal to the statesmen of the world began: "We psychiatrists, whose duty it is to investigate the normal and diseased mind, and to serve mankind with our knowledge, feel impelled to address a serious word to you in our quality of physicians." The appeal includes the statement: "If war is to be prevented the nations and their leaders must understand their own attitude towards war. By self-knowledge a world calamity may be prevented."

Polite replies to this appeal were received from many statesmen. One may speculate on the actual reaction to its reception by these men in high position—a shrug of the shoulders, a tolerant smile, a sigh over lost illusions, perhaps at best a brief detached survey of its implications. These implications have not been woven into the political thought of our times. Even the terms we use seem to have a certain significance. A government has a Ministry of Health, it does not call it a Ministry of Disease; it has a Department of Education, not a Department of Ignorance. It has a War Department. Might it be possible for it to have a Department of Peace with a constructive policy, and not concentrate exclusively on the destructive possibilities in human relations?

In the absence of such Departments of Peace the Netherlands physicians turned to the individual statesmen. While they may ride the political whirlwind, the statesmen do not always direct the storm. They may be carried along by external forces over which they have little control and by inner forces into which they have little insight. The most important forces which have influenced and continue to influence the efforts, the emotions, the beliefs of individual statesmen are not necessarily to be found in Who's Who. To the statesmen the Netherlands appeal commends self-knowledge. Could every statesman with impunity carry through a relentless self-analysis? What cabinet could stand if the self-knowledge of its members were pushed beyond a certain point? The statesman has made heavy investments and is deeply committed to certain beliefs and activities, he is entangled in a mesh of action and belief

of his fellows from which his very prominence may make it impossible to detach himself. He may be immune to a rational appeal which lays such stress on self-knowledge.

The statesman probably knows his classics well enough to quote the familiar lines, *video meliora proboque, deteriora sequor.* Knowledge and reason play a great rôle in human conduct but the statesman does not need to read his Schopenhauer to realize that the crude urges of human nature may brush aside all rational considerations and even harness man's highest endowment in the service of his lowest passions.

Thus while paying tribute to the noble impulse which inspired the Netherlands appeal to the statesmen who direct the thunderbolts, we may be a little uncertain as to how far they have control of these thunderbolts and as to whether their fixed preoccupations and official entanglements may not prevent any efficient response. Sentimental regret, however, and inaction in face of grave present needs can hardly satisfy us;

> "the sin I impute to each frustrate ghost
> Is—the unlit lamp and the ungirt loin."

The challenge issued by the Netherlands physicians may cause searching of heart, and lead to clarification of our psychiatric thought in relation not only to the issue raised by the appeal, but to other social issues.

War is a big topic, international relations are complicated, humanity is a large concept. It may be wise at the beginning to realize that the scope of our minds is limited, that few can think in international terms; we use big words and feel that we are grasping large areas of space and a wide expanse of time, but these words in actuality have a marked personal and regional quality. We fail to realize the parochial limitations of our mind but talk glibly of universal peace. In view of these limitations, with peace as with charity it may be well to begin at home. Success in dealing with the more immediate problems may fit the individual and the community to deal more adequately with the wider problems; it may even enable the statesmen to deal in a more rational and objective way with problems which involve the peace of nations.

The members of this Association in their daily work have constantly to deal with peace and war. It may be the peace of mind

of the individual that is at stake or the harmony of the family group, or it may be a question of conflict in a broader social setting. Even at the physiological level one may often formulate the physician's task as that of transforming a situation of conflict between different systems into one of harmonious cooperation. At the psychological level each human soul is an arena of combat; there is the conflict between the appetites and the ideals, between the childish and the mature, between the primitive and the cultured, between the reactionary and the progressive, between the autistic and the realistic, between the egoistic and the social. In many patients the nervous or mental disorder can be formulated usefully in such terms, and the rôle of the physician is to help the patient to establish harmony between the warring elements, a harmony which does justice to the various factors and enables the individual to play his rôle in the community life. In the searching analysis involved in this procedure the psychiatrist has a unique opportunity to study the dynamics of human nature. The increased self-knowledge is a gain to the patient. The insight into the laws of human nature gained by the psychiatrist is of practical importance for the conduct of every human life, and the formulation of this knowledge and its dissemination throughout the community is a responsibility of the psychiatrist, individually and collectively. This is to be looked on as the fundamental basis of social peace, and one may scrutinize in the community the resources available for helping the individual to attain this peace of mind.

"My mind to me a kingdom is," but peace within this kingdom is not enough; the kingdom is only part of a wider territory, and the individual fate is inextricably interwoven with that of other members of the social group. The most immediate group is that of the family. Those interested in the establishment of social peace may consider to what extent the social structure, the customs, the beliefs, the organized institutions in a community foster the harmony of family life or permit or even foster discord.

The basis of family life is marriage, whereby two people enter into one of the most important and binding contracts of their lives. Its importance is officially recognized by the necessity of civil or religious sanctions. A community interested in the welfare of the individual and in promoting harmonious family life might well

consider what are the conditions which favor a satisfactory marriage and might scrutinize the social customs and beliefs and codes which have a bearing on this basic social institution and on the preparation of the individual for accepting this responsibility. Every psychiatrist has experience of marriages, sanctioned by state and church, which from the beginning had little chance of success; in an atmosphere of warfare, overt or concealed, children born in such a marriage are brought up. Serious attention to marriage as the basis of the family involves consideration of the attitude of the community towards sex in general and study of the way in which a more honest, serious and intelligent attitude towards this life issue can be developed in the community.

With regard to the relations of children to parents, parents to children, siblings to each other, the psychiatrist has many opportunities for prolonged observation. In the individual situation he may make a useful contribution; from his accumulated experience certain general principles may be formulated, which deserve to be woven into the thought and daily practice of the community. The degree to which the psychiatrists of the community are sensitive to these issues and promote the utilization by the community of the collective observations of psychiatrists in these matters may well be a major concern of the The American Psychiatric Association.

I may here pause to crave indulgence for the use of certain terms. I have talked of peace of mind, of marital and domestic peace. These old-fashioned terms may offend more delicate ears as they bring with them vague overtones of ethical nature, are not chemically or scientifically pure. Instead of peace, whether personal or domestic, one might perhaps talk of harmony or equilibrium; or the word integration may give our homely statements the protective coloration of scientific terminology. I plead guilty also to having referred to the human soul. I leave it to anyone who finds the word distasteful to choose his own symbol for certain aspects of human experience of profound personal importance.

The family is the immediate social group to which the individual belongs, but soon he plays his rôle on a larger social stage, first as member of the school community, and later as an adult member of the general community, with complex relations to a great variety of social groups, occupational, recreational, cultural, religious.

A large part of man's waking time is passed in work. Many of his satisfactions and his frustrations are associated with his work; his beliefs, his customs, his code, his personal relations are conditioned by his work. In his study and treatment of the individual patient the psychiatrist has to study not only the fundamental biological components of the personality and the complicated balance of factors within the family circle, he has to weigh the satisfactions and frustrations in the wider social relations, among others the satisfactions which come from work. One studies the extent to which the work program is an adequate outlet for the special endowment of the patient and scrutinizes the factors involved in the personal relations included in the working environment. Here too, as within man's personal kingdom and within the castle of the home, so in the factory and on the farm, in the store and in the office, on the bench, in the pulpit, in the hospital ward and the editorial sanctum there is rivalry and conflict, with the issue of peace or war never finally settled. Man craves a certain status or prestige or self-respect, he suffers from a feeling of inferiority. He craves a certain degree of independence; he is not content to be a pawn or tool or material for exploitation. He craves the opportunity to exercise skill or power, to express himself according to the nature of his endowment. The satisfactions and activity in the workshop may balance personal and domestic dissatisfactions and tensions; on the other hand, personal and domestic difficulties may be carried over into the factory with disturbing effect. In his patients the psychiatrist may see the importance of lack of status, of a feeling of inferiority, of frustration of self-expression, of dehumanized personal relations, boredom, envy, depressive preoccupations. When these responses of the individual are subject to the astounding amplification observed in group phenomena, a community is divided against itself, labor unrest and class war take the place of friendly social cooperation. For the solution of these problems or for the amelioration of the situation a clear grasp of the human factors is essential. The less personal problems involved in production and distribution are complicated, but the psychology of the men and women involved is of equal importance. Beneath quiescent industrial situations mighty forces are often slumbering, latent discontents are accumulating, tensions increasing. It may need only a small spark, a propitious occasion, a specific point of

crystallisation, a dynamic personality, to demonstrate how unsound was the apparent equilibrium, how tenuous the social bonds, how divergent the individual interests.

The organization of an industrial society presents many difficult technical problems, but the most important general consideration is that of giving reasonable opportunities for the satisfaction of the human needs of the individuals who compose the society.

For that to be done one needs to know something of the needs of the human individual, as well as something of the resources of the community. When the social organization shows symptoms of disorder, emphasis might well be laid on studying the basal conditions underlying the symptoms rather than on directly attacking the symptoms. The number of patients admitted to mental hospitals with alcoholic psychoses is very great; the number of individuals in whose unpleasing lives chronic alcoholism plays a glaring rôle is considerable; society allows children to be brought up in sordid alcoholic homes, in an atmosphere seriously detrimental to their actual happiness and future welfare. A direct attack has been made on this symptom of social disorder by administrative efforts to eliminate or reduce the consumption of alcohol. The fundamental disorder is not touched by the treatment of the symptom. The underlying disorder is in the tensions and dissatisfactions of the individual life. These latter we must study in painstaking detail; then we can consider how help may be brought to individuals in need of help and how society can organize conditions of life which may reduce undue stresses and offer reasonable opportunities for satisfaction. No easy task; for it may involve problems of housing, wages, educational opportunities juvenile and adult of various types, opportunities for recreation, for the exercise of skill, and for the enjoyment of art.

The problem of prostitution and of venereal disease is not altogether one of bacteriology and of administrative measures. Segregation and prophylaxis may have their place. Human values are also involved; what steps can society take so that each individual shall have due respect for the destiny of his fellow being, sufficient appreciation of the values of modern culture to be willing to accept restrictions on self-indulgence as his contribution to the maintenance of that culture? No easy task.

Delinquency and crime are an obvious challenge to the complacency of society; purely repressive or punitive measures are recognized as inadequate, and earnest students of the subject have shown the relationship of these disorders to anomalies of human nature and to the imperfections of the social structure.

So whether one starts from mental disorder, from wayward or anti-social conduct, from industrial discord, racial and religious intolerance, mob violence, or national animosities, one is faced with the necessity of studying human nature and the various forces involved in organized group life.

Although one may have no illusion as to the immediate effect of knowledge and reason on the conduct of human affairs, one may still have faith in their irresistible if slow penetration. The physical world once seemed rather a muddle, full of unexplained and unpredictable events; man has elicited many of its secrets, and the control of the forces of nature thus gained has made man's life less "solitary, poor, nasty, brutish and short." Man's happiness, however, depends on more than material comforts, it depends on the nature and quality of human relations, on his attitude to the cosmos, on his response to spiritual values. In the muddled state of human affairs blind instinctive and unconscious forces will continue to be operative, but it is our task to see that rational considerations play an increasingly important rôle. Foremost among these considerations is sound knowledge of the component forces of human nature, and of the forces at play in group life.

The psychiatrist is daily accumulating facts with regard to human nature, its tasks, and its mode of reacting to these tasks. In the United States in a single year (1935) 101,462 patients were admitted to hospitals for mental disease for the first time. In perhaps 50,000 of these patients the disorder expressed some special vulnerability or instability, some difficulty in establishing harmony between the warring elements in the personality or in establishing sound relations with the immediate social group.

The psychiatrist had in each of these cases to search for any evidence of undermining disease, to study the native endowment, the complicated balance of forces within the personality, the moulding factors in home and school and job, the adaptation to the code of the community, the compromise between opposing loyalties, the sources of satisfaction available in the community, the continu-

ing or episodic stresses or deprivations. The investigation in each case had for its goal the restoration of the personal equilibrium, the restoration of the patient to the social group. For this purpose the physician had to learn to know his patient as we know few of our fellows. He had to put aside convention and disguise, to disregard the familiar excuses and evasions, to penetrate beneath the surface to the actual driving forces of the individual life. He had to scrutinize the situation, to evaluate its actual significance to the patient, its fitness for his needs, its supply of essential elements, its demands on the patient. He had to study the development of the disorder, the earlier phases of the adaptation of the individual, the increasing difficulty of maintaining the personal equilibrium, the culmination in the actual symptoms which signalled the need for help.

In such a study of the situation the physician takes up in detail the forces and the values which permeate the home, the workshop, and the general social atmosphere. He scrutinizes these factors from the special point of view of their bearing on the welfare of the human personality.

Such work with an individual patient takes the hospital physician, usually through an auxiliary worker, into the fulness of community life, into the home, the school, the playground, the job, the market place, the court, the church. He has thus the opportunity of evaluating how far the community supplies the necessary resources for a wholesome life, how far these resources may have been practically barred to the patient, how far social forces had frustrated or distorted the personality of the patient.

His insight into the social structure of the community from which his patients come may well be of peculiar value, focussed as it is not on the external aspects of the social structure but on its fitness as a habitat for the human spirit—if I may be allowed the use of this word.

In his efforts to return the patient to the community, as in his study of the prevention of such disorders, the physician has to evaluate the attitude of those individuals in the community, whose personality influences most directly the atmosphere which the patient must breathe. He has to evaluate the insight, the plasticity, the human quality of these people, of the family or the teachers, or again of fellow-workers, social companions, religious associates.

One does not know in how many hundreds or thousands of the patients admitted to mental hospitals in 1935 such a survey was actually made. What may be emphasized is the fact that these issues were presented by the patients, however they may have been met by the mental hospitals. The mental hospital has an unusual strategic position for accepting the challenge of these issues. The mental hospital in meeting its task of restoring the unbalanced to their normal tasks and of organizing a tolerant community for the mentally crippled has at the same time the opportunity of making a unique contribution to the study of concrete social issues, and to the education of its local community.

Many members of this Association are quietly and unpretentiously carrying on such investigations, and acting as a leaven in their community. It is important for the Association to take special cognizance of these efforts and to express its interest and appreciation.

The physician working in the wards or the out-patient department or the neighborhood clinic of the mental hospital may feel that the detailed study of men and women in their adaptation to the ordinary circumstances of the home and the market-place is considered a rather humdrum affair. Its general human interest is recognized, it may occasionally have dramatic qualities, it is a condition of professional work done at a respectable level. But from the point of view of recognition and prestige and even financial support this type of investigation is not quite on a par with that of his more favored colleagues working at problems of the basic sciences, using elaborate instruments of precision, utilizing the experimental method. The hospital physician may be sensitive to the charge that he is addicted to descriptive psychiatry.

"Descriptive" need not be a term of reproach; the value of description may depend upon what one describes, and how one describes it, upon the accuracy of the observations which form the basis of the description and the importance of the factors upon which observation is focussed. A description may have literary or artistic value, without having much scientific value; the author of such a description may have little interest in the significance of the facts described, he may show little discrimination between the essential and the unessential. The observer, however, who is keenly interested in the moving why of human behavior and thought, who

is sensitive to the main issues of human life, who describes with accurate detail and with a sense of porportion the sequence of events in the evolution of an individual life in its special setting, may make a valuable contribution to our knowledge of human nature.

The basic biological processes involved in human behavior are the object of intensive study, and some pin their hope for the elucidation of man's difficulties and for his salvation on the outcome of these studies; but the behavior itself, its organization, its relation to the forces of the social medium is also in itself a worthy subject of study, with its own problems, its own laws, its own practical importance. It is only in the broader setting of behavior that the full significance of the basic biological processes can be adequately conceived.

The great entomologist Fabre did not limit himself to detailed studies of structure or chemical reaction, or of the action of isolated systems. His detailed studies of this nature were in the setting of a passionate interest in the life of his favorite insects, his wasps, his beetles, his caterpillars and spiders. He spied and eavesdropped on them in their most intimate activities; he followed them through their daily routine, he dogged them from the cradle to the grave, carefully observing, accurately describing. He watched them at work, and at play, and in their workshop, he described their dressmaking and their meals, he observed them in their domesticity and in their broader social life. This descriptive entomology of Fabre, inspired by a profound sympathy for living creatures, is an outstanding scientific contribution.

Fortunately for Fabre his life-span was much longer than that of the objects of his loving study. With the psychiatrist the situation is different; in addition the objects of his study are more complicated, their social organization more elaborate. He can only do what the nature of his material permits, but he may perhaps carry some of the enthusiasm and the sympathy of Fabre into his own daily observations of man and his social organization. With these gifts he will all the more efficiently minister to the mind diseased, and help to diagnose the ailments of a society, socially and industrially sick. It may be good for him working industriously in his own hospital, with modest means, towards limited objectives, to see his work as an element in an extensive campaign, the spirit of

which inspires The American Psychiatric Association. All that this Association can do to help the staff members of our mental hospitals to realize their opportunity for service, to broaden their training, to improve the conditions under which they work is to be looked on as a service to the community as a whole and not merely as a service to a special professional group.

The worker in the state hospital will be all the more efficient if he knows that he has the reasoned support of the Association behind him as he carries on with his task of bringing self-knowledge to the individual and to the community and of helping each in its task of attaining inner harmony. He may even feel that he is actuated by the same ideal which inspired the Netherlands appeal. A society which has undergone a mental catharsis through the painful process of self-knowledge may be conscious of a certain stability and peace, and can establish its international relations on a frank and honest basis of good-will and cooperation, and can meet animosities and jealousies with an understanding attitude which may encourage self-knowledge on the part of others.

I am afraid that I have covered too much ground in this address, perhaps with rather erratic leaps. To jump from the statesmen of the world to the spiders of Provence may have exhausted you; universal peace and the peace of the individual soul may seem light-years apart. The needs of the individual in various walks of life, the real social forces and values in metropolis, manufacturing center, small town, farming community and sparsely settled areas could not be painted in.

It is the function of The American Psychiatric Association, through the continued and diversified work of its members and through the organization of its annual meetings to make the connection between the work of the individual psychiatrist and the progress of human culture, suggested in this paper, so clear that he who runs may read.

C. MACFIE CAMPBELL, M. A., B. Sc., M. D.

President, 1936-37.

A Biographical Sketch,

By WILLIAM L. RUSSELL.

Dr. Charles Macfie Campbell was born in Edinburgh, Scotland, on September 8, 1876, and obtained the major part of both his general and his professional education in this "Modern Athens." After a preliminary preparation in the celebrated George Watson Boys' College, he matriculated at the university in 1893. There he remained in attendance for nine years, following various courses to his ultimate goal in medicine. The summer of 1896 was spent studying in Paris, and in the following year he received from the university the degree of M. A. with first class honors in philosophy. He spent the summer of 1897 in Germany studying the language, and upon his return he entered upon the study of medicine. In 1900, he received the degree of B. Sc., with distinction in anatomy, physiology, and anthropology. The summer of 1901 found him again in France, in the clinic of Professor Raymond at the Salpêtriere.

In 1902, he was graduated in medicine with the degrees of M. B. and Ch. B. (*summa cum laude*). He was awarded the McCosh Graduates and Medical Bursaries, and, his preferences in medicine having become clear, he spent the next year in studying neurology and psychiatry; from September, 1902, to April, 1903, at the Bicêtre with Pierre Marie, and attending Babinski's Clinic, and from April to September 1903 in Nissl's laboratory at Heidelberg, and in attendance of courses by Erb, Hoffmann, Kraepelin, and von Hippel. In September he was back in Edinburgh as a resident at the Royal Infirmary, and helping Alexander N. Bruce in a study of the intermedio-lateral tract.

Dr. Campbell had been to America for a short visit in 1893, and, in 1904, the offer of a position as interne in the Pathological Institute (now Psychiatric Institute) of the New York State Hospitals, of which Dr. Adolf Meyer had recently become director, was sufficiently inviting to lead him to accept. He was soon advanced to the position of assistant physician and remained until 1907, when

he resigned to accept a corresponding position at the Royal Edinburgh Asylum (now Hospital), of which Sir Thomas S. Clouston, M. D., was director. A strong magnet that had turned him back to Scotland was revealed on June 3, 1908, when he married Jessie Deans Rankin of Glasgow, who was also a physician. It was in 1908 also that he became a member of the Royal College of Physicians of Edinburgh (M. R. C. P. Edin.).

In the same year, the lure of the wider opportunities of America was again held out to him and he returned to the institute in New York in the position of associate, and instructor in psychiatry at Cornell University Medical College. There he remained until 1911, when, pending the opening of the Phipps Psychiatric Clinic of Johns Hopkins Hospital, Baltimore, of which Dr. Meyer had been appointed director, he resigned and accepted the position of first assistant physician at Bloomingdale Hospital (now New York Hospital —Westchester Division) at White Plains, New York. In that year also he submitted to the University of Edinburgh his thesis on "Focal Symptoms in General Paralysis," based on studies he had made at the institute, and received the degree of M. D.

The following two years were spent at Bloomingdale, studying and treating patients; and making a lasting contribution to the reorganization and quickening of the service for the more active plans of work that had been adopted by the governors. Dr. Campbell's earliest contributions to medical literature were neurological. In 1908, however, he published an article on "Psychological Mechanisms with Special Reference to Wish Fulfilment," and, in 1911, one on "The Rôle of Psychoanalysis in Psychiatry." While at Bloomingdale, where the cases were nearly all functional, he paid particular attention to the psychological aspects, making special use of association tests. In 1912, he published an article on "The Application of Psychoanalysis to Insanity," and in 1914, when Volume II of the Pathological Institute "Studies in Psychiatry," was issued it contained an article of his on "The Mechanism of Some Cases of Manic Depressive Excitement."

In 1913, he joined Dr. Meyer at the Phipps Clinic in the position of associate director, and associate in psychiatry (1914, associate professor of psychiatry) of the Johns Hopkins Medical School. There he spent seven productive years, in hospital and out-patient clinical work, in scientific investigations, and in teaching and writ-

ing. During this period he published 17 articles that reveal the trend and growing breadth of his interests and efforts; the subjects being clinical, including child psychiatry and psychiatry in general medical practice. One of these articles was based on the study of the children in a Baltimore school district.

During the war, Dr. Campbell was, for a short period, a private in the U. S. Army. His principal contribution in war service was, however, as a civil surgeon, in the intensive training, at Johns Hopkins Hospital, of physicians preparing for neuropsychiatric work in the army. He also spent some time at a special army hospital at Lakewood, New Jersey, studying the heart disorders of soldiers. This study was the basis of his article on "The Rôle of Instinct, Emotion, and Personality in Disorders of the Heart" that was published in the Journal of the American Medical Association in November, 1918.

He grew steadily in professional stature and reputation so that, when, in 1920, Dr. E. E. Southard, director of the Boston Psychopathic Hospital and professor of neuropathology of Harvard Medical School, died, Dr. Campbell was appointed as director of the hospital and professor of psychiatry in the medical school. In these positions, which he still holds, his career has been one of increasing usefulness and distinction. Besides attending to the exacting duties of his position, he has given much time and effort to the advancement of psychiatry and mental hygiene in the general medical profession and in the general body of knowledge and social standards. He was, for 10 years, president of the Massachusetts Society for Mental Hygiene. He is a member of the National Committee for Mental Hygiene, and of the Advisory Committee of its Division on Psychiatric Education. He is also an honorary vice-president of the International Committee. He is a fellow or member of all the leading local and national psychiatric societies, and was president of the American Psychopathological Society in 1918, of the Boston Society of Psychiatry and Neurology in 1924, and of the Massachusetts Psychiatric Society in 1933. He has been a member of The American Psychiatric Association since 1917, and has made valuable contributions to its programs. He is also a member of the British Medical Association, a corresponding member of the Royal Medico-Psychological Association, and of the Section of Psychiatry of the Royal Society of Medicine of

Great Britain, and of the Société de Neurologie de Paris, and honorary member of the Nippon Seishin Shinkei Gakkwai (Japanese Society of Psychiatry and Neurology). He is also a member of the principal local and national general medical societies, of the Eugenics Research Association, and of the History of Science Society, a fellow of the American Academy of Arts and Sciences, and honorary fellow of the Institute of Medicine of Chicago.

In 1924, Dr. Campbell was invited to deliver the Shattuck Lecture before the Massachusetts Medical Society, and chose as his topic, "Psychiatry and the Practice of Medicine." In 1927, he delivered the Pasteur Lecture before the Chicago Institute of Medicine, in 1933, the Gehrmann Lectures at the University of Illinois Medical School, and the Lowell Lectures at the Lowell Institute, Boston, and in 1935 the Salmon Memorial Lectures at the Academy of Medicine, New York. Some of these lecture series have been published in book form under the titles: "Delusion and Belief," "Towards Mental Health," "Destiny and Disease in Mental Disorders." Dr. Campbell also contributed the chapter on "The Treatment of Dementia Præcox" in White and Jelliffe's well-known treatise, the chapter on "Mental Disorders" in Cecil's Textbook of Medicine, a chapter in the "Contributions to the Study of the Personality," published in honor of Dr. Morton Prince in 1925, a chapter in the study of the Problem of Mental Disorder made by a committee of the National Research Council, and a chapter on "Mental Hygiene and Education" in "Social Aspects of Mental Hygiene" (Yale University Press 1925). His Lowell lectures on "Human Personality and Environment" were published in 1934. His contributions to current psychiatric literature have been numerous and on various topics, with clinical studies, psychiatric education, and mental hygiene predominating. As a speaker and teacher he is impressive, interesting, and stimulating, and, in that way has contributed more to psychiatry and mental hygiene than has appeared in his publications. Few psychiatrists have, with such a sturdy mental alertness and openmindedness, maintained a more steady equilibrium amid the cross currents of modern psychiatric thought and practice than Dr. Campbell. His sound practicality, his breadth of knowledge, and his philosophic grasp, as well as his clearness of thought and expression, are well shown in his recent address as President of The American Psychiatric Association.

A NOTE ON THE URINARY PHOSPHATE OF NIGHT URINE IN MENTAL DISEASE.*

By WALTER MICHAEL BACHINSKI,
AND
JAMES JAMIESON RAE, PH. D.,
Brandon, Manitoba

The large amount of phosphorus containing compounds in brain and nervous tissue and their universal distribution through all living cells has led to much research as to the rôle of phosphorus in animal metabolism. It is known that the compounds of phosphorus play an essential part in the metabolism of fat, carbohydrate and protein. They are also fundamental to such physiological processes as the contraction of muscle, the ossification of bone and permeability of cell membranes.

The average diet contains a great variety of phosphorus compounds, viz.: inorganic phosphates, phospholipids (lecithin and kephalin), phosphoproteins (caseinogen of milk) and the simpler organic esters, such as glycerophosphates and hexosephosphates. Since phosphorus compounds are found abundantly in nerve tissue and since they form a considerable portion of the average diet, it was thought advisable to investigate the possible relationship between mental disease and the urinary excretion of organically bound and inorganic phosphate.

Mairet (1884) in studying the phosphorus metabolism of manic-depressives found an increased total urinary phosphate excretion over normal in both the agitated and depressed states. Lailler (1884) found that in acute delirium or mania there was a marked

* From the Department of Chemistry, Brandon College.

Our thanks are due to Dr. T. A. Pincock, Medical Superintendent of the Brandon Hospital for Mental Diseases, for permission to procure the urine samples, for use of the library and access to the files of that institution. To Dr. Creasy and Dr. Little, from the same institution, our thanks are also due for advice and criticism in preparing this article.

We wish to express our thanks to the Banting Research Foundation for a grant to one of us to defray the cost of apparatus and chemicals.

excess of phosphorus in the urine, in hypomania a slight excess only, while in mild depression the urine was normal. After making a careful study of the urines of insane patients and numerous controls, Folin, Shaffer and Hill (1904) concluded that there was insufficient experimental data recorded in the literature to warrant any connection between the urinary phosphate excretion and mental disorder.

In studying the excretion of phosphoric acid in urine in the psychoses, Tsuchiya (1924) found in neurasthenics an average excretion 2.4 times the normal. In eighteen manic-depressive cases there was an average increase of twice the normal, both in excited and depressed states. The examination of five epileptic specimens before and shortly after an attack gave low values preceding and high values shortly after the fit, with an average about twice the normal. In dementia præcox the values were close to the normal, while in excited catatonics the average was about twice normal.

More recent work by Weil and Liebert (1937) on the phosphorus content of the blood serum during an epileptic seizure in man has shown that during the seizure the inorganic phosphate content of the serum was increased by 34 per cent. Analyses of the blood serum were made during the aura preceding the convulsion, during the attack itself, and after the seizure. Experimental injection of rabbits with an emulsion of thujone produced convulsive seizures and an accompanying increase in the inorganic and organic phosphates of 98 and 37 per cent respectively. Upon administering curare into the muscles, further injections of thujone did not affect the phosphate content. Their final conclusion was that in man the tonic-clonic contractions of the muscles during an epileptic fit are the source of the increased serum phosphate.

In view of the indefinite results reported by various workers in literature regarding the urinary excretion of phosphate in the psychoses it was thought advisable to investigate the matter more fully using improved methods of analysis and noting at the same time any abnormal physical or pathological condition of the patient in addition to his true mental type. It was further noticed that many of the previous workers were quite ambiguous in their use of nomenclature for the various mental types examined, and in view of recent advances in experimental psychiatry much more care has to be given to this phase of the problem.

Experimental Work.

The inorganic phosphate present in the urine was estimated using King's (1932) method. Rae's (1936) modification of Youngburg and Pucher's (1924) method for the determination of organic phosphate was followed with satisfactory results. All samples of urine were collected in the morning between 5 and 7 a. m. and represent the night urine.

(a) *Inorganic Phosphate.*—To 0.2 cc. of the urine in a 25 cc. volumetric flask distilled water was added up to 10 cc. 2 cc. of 60 per cent perchloric acid, 1 cc. of 8.33 per cent ammonium molybdate and 1 cc. of 0.33 per cent amino-naphthol-sulfonic reagent were added, and water up to 25 cc. A standard containing an appropriate amount of phosphate was prepared in the same way at the same time. The contents of the flasks were shaken and after five minutes the colors were compared, using a Duboscq colorimeter.

(b) *Organic Phosphate.*—The feasibility of this method depends upon the complete precipitation of the inorganic phosphate. To do this 10 cc. of the urine was treated with a calculated excess of magnesia mixture (magnesium chloride, ammonium chloride solution) without added ammonia (0.16 cc. magnesia mixture for each mg. of inorganic phosphate present), and an equal volume of normal ammonium hydroxide. The mixture was well shaken and allowed to stand for ten minutes (pH 8.8-9.0). After filtering, 3 cc. of the filtrate was used for the organic phosphate analysis. The filtrate was tested for the complete precipitation of inorganic phosphate by method (a) above. 2 cc. of 60 per cent perchloric acid was then added to the organic phosphate sample, and the mixture digested on an electric heater. A drop or two of nitric acid was added to hasten the oxidation of organic matter. The contents of the tube were then cooled and transferred with washing into a 25 cc. volumetric flask. 0.2 cc. of perchloric acid was added to make up for loss of acid by evaporation. The procedure from then on was the same as the inorganic phosphate analysis. The results obtained are given in Table I. (All the patients were males.)

Conclusions.

1. The normal urinary phosphate excretion as determined by Rae (1936) was inorganic phosphate 102 mg./100 cc. and organic

PROPERTY OF PSYCHIATRIC INSTITUTE

phosphate 1.20 mg./100 cc., using 24 hour samples. It must be remembered that the urines obtained were overnight samples and that comparison with normal 24 hour samples is of rather doubtful significance. Since it was impossible to collect 24 hour samples due to incontinence and the types of patients studied, the results are significant only when compared with each other. The facts that night urines only were used (thus eliminating the active exercise factor), the patients were all on the same diet, and the samples were all collected within a few weeks, would tend to lend significance to these results. The average values for the group examined (58 patients) were 78 mg./100 cc. of inorganic phosphate; 1.20 mg./100 cc. of organic phosphate and 1.78 for the O.P./I.P. ratio.

2. In the schizophrenics the values obtained were so diverse as to make an average value almost meaningless. However, patients in the catatonic state seem to exhibit slightly higher values than those in the paranoid state.

3. In the manic-depressives the average values for the depressed state were: I.P. 43.9; O.P. 1.07; O.P./I.P. 3.09, and for the manic state I.P. 108; O.P. 0.84; O.P./I.P. 0.79. These results differ from those obtained by some former workers who claim an increased urinary phosphate excretion in both the manic and depressed states of the psychosis, in showing a decrease in the depressed state with increased excretion in the manic state.

4. In the senile group there is also a lowering of the inorganic phosphate.

5. In the other psychoses tabulated and in the general paralysis of the insane group there are no marked deviations from the average values.

6. Although it was hoped in this research to find some connection between a specific mental disease and phosphorus excretion, the results indicate that only in those psychoses in which there is a marked difference in muscular activity is there any change in the urinary phosphates. The authors would also like to point out that due to the rather large differences in the individual values obtained previous work of this nature done only on a few patients is inclined to be of limited significance.

THE EFFECT OF BENZEDRINE SULPHATE ON CERTAIN ABNORMAL MENTAL STATES.*

By PURCELL G. SCHUBE, M. D., M. C. McMANAMY, M. D., C. E. TRAPP, M. D., AND A. MYERSON, M. D.

Recently Peoples and Guttmann [1] reported a study on the effects of benzedrine on man. In this study they noted that benzedrine had certain psychological effects, *i. e.,* that it produced an increased tendency to talk, especially in depressed persons, some motor restlessness, and a change in mood in the direction of euphoria. Prior to the publication of the above paper Myerson had noted that frequently he obtained in normal individuals, in mildly depressed and in psychoneurotic persons, and in normally fatigued persons, certain distinctly beneficial results following the administration of benzedrine. An oral dose of 10 to 20 mg. of benzedrine would produce a warm glow of the body which was quite agreeable and which was associated with a sense of relaxation, and at the same time a disappearance of the drowsy, tired feeling around the face and eyes. There was established a sense of calm which was quite gratifying and pleasing, a lessening of any distress or depression, and an increasing feeling of the possession of energy to be used up, a desire to do things. It appeared that in these individuals benzedrine had permitted the replacement of a group of undesirable symptoms by a group of highly desirable ones; that in persons, normal and mildly abnormal, benzedrine was definitely beneficial because it permitted the existence of a physical or mental state which was conducive to a more adequate and satisfactory social adjustment. In a recent paper Myerson [2] has incorporated this material and has included case reports showing that the depressed, restless, agitated, and fearful states, feelings of unworthiness, feelings of inferiority and fatigue, in individuals with anhedonic neuroses or minor stages of the psychoses of the same general type, were relieved of these symptoms to a great extent as

* From the Psychiatric Clinic and the Research Laboratory of the Boston State Hospital, Boston, Mass. Aided by grants from the Commonwealth of Massachusetts and the Rockefeller Foundation.

long as the use of the benzedrine was continued, but that they reappeared upon its discontinuance.

At the time that Myerson was making this study, we began to investigate the effect of benzedrine on those individuals who possessed major psychoses and who were sufficiently psychotic to necessitate hospital treatment. It is the purpose of this paper to report our findings.

METHOD.

The persons used in this study were routine admissions to the Psychiatric Clinic of the Boston State Hospital. They were free of any demonstrable organic pathology. Both male and female patients were used. They were divided into three groups. Group 1 received benzedrine sulphate in daily single doses of 10 mg. by mouth for 30 days. Group 2 received 10 mg. of benzedrine sulphate in 2 mg. doses by mouth every two hours for five doses daily for 30 days. Group 3 received 10 mg. of benzedrine sulphate in one single subcutaneous injection daily for 30 days. There was also a small fourth group which received 30 mg. of benzedrine sulphate subcutaneously daily for 14 days. In the periods before, during and after the benzedrine sulphate administration the mental and physical state of the individual patient was studied.

In the entire series there were 80 patients. In Group 1 there were 25 patients: 10 dementia præcox, 12 manic-depressive, depressed, and 3 psychoneuroses, neurasthenic; 15 males and 10 females. The age range was 20 to 48 years. In Group 2 there were 25 patients: 8 dementia præcox, 15 manic-depressive, depressed, and 2 psychoneuroses, neurasthenic; 13 males and 12 females. The age range was 18 to 55 years. In Group 3 there were 25 patients: 15 dementia præcox, and 10 manic-depressive, depressed; all males. The age range was 17 to 50 years. In the fourth group there were 5 patients, all dementia præcox; all males. The age range was 22 to 35 years.

RESULTS.

Group 1.—In this group there was no improvement; five patients (4 females, 1 male) became worse, and in four of these patients (3 females, 1 male) the drug had to be discontinued because of the severity of the reaction of the patient to the drug.

Group 2.—In this group there was no improvement; seven patients (4 females, 3 males) became definitely worse, and in three of these patients (2 females, 1 male) the drug had to be discontinued because of the severity of the reaction.

Group 3.—In this group there was no improvement, and two patients, both females, became worse necessitating discontinuance of the drug.

Group 4.—In this group there was no improvement and one patient, a male, became progressively worse under treatment so that the drug had to be discontinued at the close of nine days. This individual died some months later of bronchopneumonia, and although it is possible that the benzedrine might have contributed to his death, since all of the other individuals used in the study are at the present alive and healthy, this is highly improbable.

Thus, of the 80 patients treated with benzedrine sulphate none improved, 14 became definitely mentally worse as long as the treatment was continued, and one continued worse after the treatment was discontinued until his death some months later. Of those patients who reacted badly to the administration of the drug 10 were manic-depressive, depressed (7 females, 3 males), 2 were psychoneuroses, neurasthenic (2 males), and 3 were dementia præcox (3 males).

In addition to the above findings relative to the effect of the drug upon the abnormal mental state several other observations of a physiological nature were made.

Thus, in 10 cases the use of the drug had to be discontinued because of the nausea and vomiting which followed its oral ingestion.

In two patients there were attacks which appeared to be cardiac following the administration of the drug.

In two patients there followed a period of definite drowsiness and subsequent profound sleep from which the individuals could be roused, but upon arousal complained of great fatigue.

In five patients there was a very definite loss of appetite and subsequent loss of weight during the course of the drug administration.

In nine cases administration of the drug produced definite constipation.

In three cases vertigo and pains in the head were complained of.

In those cases which became mentally worse under treatment there was an increase in the physical activity ranging from nervousness and finger-nail biting to pacing, fighting, shouting, screaming, and in one case board-like rigidity. In one individual there resulted a definite persistent suicidal drive. The increase in emotional activity in these cases ranged from a simple accentuation of depression to apprehension, fear, fright, marked desire to die, feelings of punishment, hatred and a marked increase in paranoid delusions. The somatic sensations complained of were headache, vertigo, dry mouth, shortness of breath, precordial pain, "pounding heart," "lead-like" heart, etc., emptiness of stomach, "all-gone" feeling in abdomen, and constipation.

Brief protocols of a few cases are presented below.

PROTOCOLS.

CASE 1.—A young woman, aged 27 years, was having her first attack of depression which was reactive and agitated in type. Physically she was somewhat restless; she paced back and forth and could not sleep. Mentally she was depressed, confused and disoriented. On May 7 she was started on benzedrine sulphate, 10 mg., by mouth, in single daily doses. On May 9 she refused to eat, became more restless and agitated, and refused to remain in bed at night. On May 11 it was necessary to tube-feed her. She was noisy and very disturbing to the entire ward both during the day and at night. She continued progressively worse until May 23 when she began to rush about, was extremely excited, tense, agitated, and apprehensive. She would repeatedly clutch her heart and shout, "I did it, I did it; God hates me; I made a terrible mistake" and "I am responsible for all evil." The drug was discontinued and within 48 hours she had reverted approximately to her original mental state.

CASE 2.—A young man, aged 35 years, was diagnosed as a psychoneurosis, neurasthenic type. Physically he was quiet and cooperative. Mentally he was somewhat depressed due to his many somatic complaints of which he had never under any circumstances been relieved. On May 28 he was started on benzedrine sulphate, 10 mg., daily, in single doses, by mouth. On June 3 he began to complain more vigorously of his heart, saying that it felt "dead." On June 7 he said he felt as if his stomach were bloated and he knew that it was much worse than before. On June 9 he complained that, strain as he would, he had no bowel movement. On June 10 he began to get drowsy about one hour after he had taken the benzedrine. By June 12 he was sleeping soundly all morning and when awakened he would complain of great fatigue and tiredness and that he could not stay awake. On June 15 he was obviously becoming nervous and stated that he felt "shaky inside." He was greatly

concerned about these new symptoms, all of which were alien to his original state. The drug was discontinued and in five days he had reverted to his original neurasthenic condition.

CASE 3.—A young man, aged 25 years, was having his second attack of depression. Physically he was slowed up and occasionally had periods of complete immobility. Mentally he was depressed, confused, apprehensive and afraid. On March 2 he was given benzedrine sulphate, 30 mg., in daily single subcutaneous doses. He showed no change for three days. On March 5 he appeared more frightened, more slowed up physically and would not talk. On March 7 he was definitely afraid, his eyes were staring, and he was physically immobile and mute. By March 10 he was entirely rigid, his eyes were wide and staring and it was necessary to tube-feed him. The drug was discontinued but his physical and mental condition continued unchanged. He lost weight regardless of the tube-feedings and had to be kept in bed where, in spite of care, he developed bed sores. This state continued. He became progressively worse physically and after about five months he developed a bronchopneumonia and died. There was no autopsy permitted.

CASE 4.—A young man of 37 in his first attack of depression. Physically he was quiet and prone to move as little as possible. Mentally he was depressed and withdrawn from group activities. On April 15 he was started on benzedrine sulphate, 10 mg., by mouth in single daily doses. On April 17 his appetite, which had always been good, began to fail. On April 18 he began to get nervous and to bite his finger-nails. On April 20 he had isolated himself entirely from others and stared into space for long periods. On April 22 he complained of a general feeling of discomfort and uneasiness, was somewhat confused and could not eat at all. He began to loss weight. On April 24 the drug was discontinued. On April 29 he was eating again and had reverted to his original mental state.

CASE 5.—A woman of 42 in her first attack of depression. Physically she was slowed up and retarded. Mentally she was depressed and unhappy. On May 29 she was started on benzedrine sulphate in 2 mg. doses every 2 hours for 5 doses, by mouth. On May 31 she became definitely more depressed and listless and it was necessary to spoon-feed her. On June 1, she at first became confused and then stuporous and had to be dressed and undressed. On June 2 she was mute and rigid. Her respirations were rapid and shallow and came in gasps. Her pulse was rapid and scarcely palpable. Her heart sounds were snapping in quality. She appeared very sick and frightened. The drug was discontinued and on June 4 she had reverted to her original mental state. When questioned about the episode of June 2 she said she had had precordial pain, was apprehensive and afraid and thought that she was going to die.

CASE 6.—A young man of 23 was diagnosed as a case of dementia præcox. Physically he was normal. Mentally he possessed a bizarre set of badly organized delusions with abnormal affect. He had always been cheerful and

cooperative. On February 15 he was started on benzedrine sulphate, 10 mg., by mouth in daily single doses. On February 19 he became irritable and restless. On February 20 he was so disturbed he had to be restrained. While in restraint he was extremely excited and tore at his restraint. On April 21 he became so violent that he broke his restraint and made a definite suicidal attempt. He stated that he was determined to kill himself and would do so at the first opportunity. It was necessary to watch him closely all of the time because it was so obvious that he meant what he said. The drug was discontinued on April 23 and within 24 hours he had reverted to his original mental state with a loss of desire to die.

SUMMARY.

1. A study of the effects of benzedrine on certain major psychoses is presented, thus corroborating a previous report by Myerson.[2]

2. There was no improvement in any case.

3. In 15 of the 80 cases studied there was temporary accentuation of the psychosis.

4. Benzedrine sulphate was of no value in the alleviation of the psychoses in the cases studied.

DEFINITION OF CHILDHOOD IN PSYCHIATRIC LITERATURE.*

By CHARLES BRADLEY, M. D., East Providence, R. I.

It has for some time been a matter of comment that the exact ages covered by the psychiatrist's concept of "childhood" have been far from standardized. The confusion in this matter was recently called to our attention during a review of the literature on schizophrenia in children.[1] In this literature many "children" are reported whose ages range anywhere from infancy to 18 or 20 years.

Without wishing to detract in the slightest from the value of any report or to criticize any of the authors' concepts, we might quote from the literature some rather typical examples of the confusion as to what properly constitutes a child. In one excellent report entitled "Ten Problem Children who later became Psychotic" Mooney and Witmer[2] included five patients who were over 15 years of age and three more who were 13 and 14 years. In another valuable contribution to the study of functional psychoses in childhood Kasanin and Kaufman[3] selected for their study all individuals under 16 years of age admitted to the Boston Psychopathic Hospital over a certain period of time. In a detailed discussion of 25 of their patients whom they considered as children only one was 12 years of age and the remainder 13, 14 and 15. Mental hospital records seem to be a frequent source of data in studies of this sort, and it seems quite customary to consider as children all patients under the age of 15 or 16 years. Potter[4] in a fairly recent review of the literature on schizophrenia in children notes: "it was found that the term 'children' was used rather loosely and included patients with ages as high as 16 and 17 years."

There would seem to be little question that most physicians consider childhood the period of life up to the time of puberty. This

* Studies leading to this report were aided by a grant from the Committee for Research in Dementia Praecox founded by the Supreme Council, 330, Northern Masonic Jurisdiction, United States of America.

From the Emma Pendleton Bradley Home.

commonly accepted view is entirely substantiated by technical definitions of the term. Such a standard definition appears in a recent edition of the Concise Oxford Dictionary where childhood is defined as "child state; from birth to puberty." [5] The Encyclopedia Britannica, while not specifically defining childhood, mentions adolescence as "the term now commonly adopted for the period between childhood and maturity." [6]

The pediatrician, a specialist whose practice is primarily limited by the age of his patients, customarily deals with children up to the age of adolescence. Moreover, the conventional upper age limit for most pediatric hospital services coincides with the common age of onset of puberty, namely 12, 13, or at most and infrequently, 14 years. The implication, quite apparently, is that adolescence introduces new medical problems, many of them distinct from those appearing in childhood.

In psychiatric work emphasis is naturally not so much upon the age of the patient under consideration as his mental characteristics. Therefore, in standard text books we find a little different concept of the period of childhood from that which has just been mentioned. Kanner [7] states childhood "includes all the ages between the neonatal period and the termination of puberty." Stevenson and Smith [8] in reviewing the common practices of child guidance clinics note that most of the patients come for study between their fifth and fifteenth year. Certain other psychiatric institutions dealing with children are governed by a correspondingly wide concept of the period of childhood as including individuals up to 16 and 17 years of age.[9-10] However, Potter [11] states that at the New York State Psychiatric Institute experience shows that it is practical to include in a children's unit only those patients up to the time of puberty or about 14 years of age.

The psychoanalytic worker has perhaps a more definite idea of childhood which, however, for him includes an even wider range of ages. Anna Freud [12] states: "psychoanalysis distinguishes three different periods in the life of a child: early life up to about the age of the fifth year; the latency period to the beginning of the prepuberty stage about the 11th, 12th, or 13th year; and puberty which leads into adult life."

It must not be concluded that these random observations have been cited in an attempt to suggest under the guise of authority

what cases may properly be included in any particular clinical approach or bit of research. The variability of available reports, however, strongly suggests the need of some commonly accepted definition being used so that workers may have a mutual understanding of what is meant by childhood. For the psychiatrist as well as the pediatrician adolescence has its own special probems. Our understanding of these problems would be clearer if they were considered separately and not discussed as phenomena of childhood.

Adolescence is, of course, a period ushered in by increased activity of the endocrine glands, particularly the gonads, and characterized by the first appearances of sexual maturity. So far, however, we have no way of recording precisely the exact onset of this activity so that any attempt to limit "childhood" on a strictly physiological basis would probably result in even more confusion than now exists.

Any single criterion of the term "childhood" must, if it is to be readily and widely accepted, have the virtues of simplicity and clarity. An example which we may well follow in this regard is that of the pediatrician and the children's hospital to whom for classification purposes at least the "child" is an individual below a definite age level. This age level had best be that which most nearly coincides with the onset of physiological puberty and both tradition and experience suggest the thirteenth birthday.

We would, therefore, urge, for the purpose of psychiatric discussion wherein mental disorder is specifically considered because of its relation to childhood, that only individuals of 12 years and under be described as children. This practice should successfully eliminate the present confusion existing in psychiatric research and in the literature.

SIX YEARS EXPERIENCE WITH NARCOSIS THERAPY IN PSYCHIATRY.*

By HAROLD D. PALMER, M. D.,
AND
FRANCIS J. BRACELAND, M. D.,
Philadelphia.

In January 1930 at the Pennsylvania Hospital a study of prolonged narcosis as therapy in the psychoses was begun. Twenty-six patients were treated and the results, as well as the follow-up, are expressed in Table I.

There is no question but that prolonged narcosis does something fundamental to the psychotic structure. Frequently, the disruption of the psychotic mechanisms is sufficient to allow the patient to make a permanently better adjustment or a complete recovery (81 per cent of the original series improved or recovered).[1] The following brief abstracts will illustrate the degree of interference with the psychoses.

CASE 72.—Female, age 43. Diagnosis: manic-depressive, depressed. Three previous periods of depression averaging about six months in length. Three years ago at age 40 the patient developed a severe depression which continued unchanged for the entire three year period. Psychosis was marked by negativism, mutism and periods of stupor. Treatment was begun in January 1930 and during the first intravenous injection of sodium amytal the mutism which had existed for nine months disappeared and during the semi-somnolent stages the patient talked freely and inquired into the nature of the treatment and remained cooperative throughout 10 days of narcosis. On emerging from treatment, she was for a brief time euphoric and over optimistic but improved gradually to a state of complete recovery and was discharged. She has remained well since the treatment.

CASE 5.—Male, age 24. Diagnosis: catatonic schizophrenia. Heredity badly tainted with mental disease. Patient was an only child, delicate, quiet, did not mix well and was over studious. During adolescence was not sociable, lacked humor but was able to finish professional collegiate training. During

the first year of his professional training he became more withdrawn, seclusive, and gradually developed a threatening, suspicious attitude and became psychotic. He was resistive, destructive, irritable, had the delusion that he was God, that his parents were not his own. In the hospital he was nude,

untidy and there were outbursts of impulsive violence and aggressiveness. He was given the sodium amytal narcosis treatment and during the semi-somnolent states he was mentally lucid and cooperative. During the week following the treatment, he discussed his professional interests, talked with several of his associates, showed complete insight and two weeks after the comple-

tion of the treatment he was discharged. He spent three months vacationing at the seashore and then returned to his professional duties and is now (seven years later) doing well in his social and professional relationships.

CASE 87.—Female, age 43. Diagnosis: severe compulsion neurosis. Patient had been ill for 18 years, her life became gradually constricted to a point where she was definitely asocial. There have been periods of acute anxiety and panic and for a year the patient was unable to accept psychiatric treatment She was given the narcosis treatment in March 1937 in an effort to break up the progessively destructive trend. She emerged from the treatment euphoric, had good insight, and was able to break through the powerful resistance which she had shown before the treatment and was able to reveal the basis for her compulsive thoughts. There was a return of some of the compulsive ideas but the patient had insight, was more accessible to psychotherapy and with help has broken through many of the restrictions imposed by her condition. Her psychiatrist believes that the prognosis has been definitely changed in a favorable manner by the treatment.

We wish to report at this time the results of 100 cases selected from a somewhat greater number of patients receiving large doses of sodium amytal or other sedative preparations and various modifications of the narcosis treatment. The 100 cases received the more or less standardized "prolonged narcosis therapy" as later described in a discussion of technique. The cases are divided as shown in Table II.

LITERATURE.

The induction of anesthesia or of deeply somnolent states in an effort to dislodge psychotic mechanisms is a relatively ancient procedure in psychiatry. The first report in modern times is that of Greisinger,[2] who, in 1882, described a number of recoveries and many remarkable improvements, in psychotic states, following deep sleep induced by various anesthetics and narcotic substances. There is evidence to show that at that time the treatment was known to medicine for 50 years or more. In 1900 Rigg [3] and McLeod [4] reported the results of massive doses of bromides in cases of acute mania. Trional was used in 1901 by Wolff [5] with no particularly dramatic results. Klaesi [6] was the first to report a well standardized narcosis therapy and in 1922 he reported favorably on the treatment of a fairly large number of cases. He described the mental catharsis which has been mentioned in his subsequent papers on the subject following the administration of somnifene. He urged the use of psychotherapy during the induction phase. The results obtained by Oberholtzer [7] and others are summarized in the Table III.

In this country Bleckwenn [8] obtained encouraging results in the treatment of neuro-psychiatric conditions by the use of sodium amytal. His work has been the basis for many therapeutic endeavors with various modifications of narcosis treatment. Merloo [9] stressed the value of the treatment in revealing factors in psychopathology. He believes that narcosis treatment is a constructive therapeutic force and should be employed widely. Magnus,[10] in 1934, reported his results with dial and felt that the treatment is of great value. MacNiven,[11] Hennelly,[12] Strom-Olsen and MacCowan [13] use insulin and glucose before, during and after the treatment and believe that it is essential in combating the ketosis which accompanies the somnifene narcosis. Their results are summarized in Table III. Lorenz, Reese and Washburne [14] reported in 1934 their observations during intravenous injection of sodium amytal in 350 cases. They believe that sodium amytal, properly prepared and properly administered, produces no alarming physiological effects. Horsley,[15] in 1936, used the term "narco-analysis" in describing a combination of narcosis treatment with psychotherapy. He believes that light narcosis with intensive psychotherapy is a quicker and more effective therapeutic procedure than psycho-

analysis. He finds that during the narcosis a state of passive receptivity is produced in which free association can be carried out with facility because of the removal of inhibition and the restoration of faded memory. Cloetta and Maier [16] introduced a new preparation in 1934 which has been widely used in Switzerland. Our results have not been particularly brilliant with this preparation. Broder [17] described in 1936 an abridged method for the use of sodium amytal in mental disease which seems to be particularly encouraging. In 1937 Swanson, Weaver and Chen [18] studied the physiological effects of amytal in animals and report no evidence of tolerance nor withdrawal symptoms and they conclude that the administration in animals is not followed by pathological organic changes, habit formation, tolerance or withdrawal symptoms. Kanterovitch,[19] Alexander,[20] Thorner,[21] Parfitt[22] and others have contributed very helpfully to the literature on the subject.

Technique.

The technique which has become standardized at the Pennsylvania Hospital is as follows: The *object* is to keep the patient asleep or deeply somnolent for 15 to 20 hours daily. Two periods during the 24 hours are allowed for feeding and attention to bowel and bladder functions, routine nursing care, etc. The duration of the treatment averages from 10 to 12 days.

1. A preliminary study is of great importance, in which thorough psychiatric, neurological, physical and laboratory investigations are carried out before the treatment is begun. We emphasize, particularly, search for foci of infection which may become ignited during the treatment.

2. All cases are tested with several doses of three to six grains of sodium amytal for idiosyncrasy to the hypnotic drug. Observations of pulse rate and quality, respirations, blood pressure, evidences of cyanosis and other signs of cardiovascular embarrassment are made.

3. The narcosis phase is begun with doses of three grains of sodium amytal given orally every three or four hours. Having once produced a satisfactory degree of somnolence the dose is so regulated by oral or rectal administration that the patient is kept at the desired level. It is necessary to increase the dose rather

sharply from day to day until the fourth day, when a plateau is reached, until the tenth day and then gradual withdrawal is accomplished by halving the dose, *e. g.*, 72-36-18-9. The highest dose given was in case 57 (a "manic-schizoid") where 220 grains a day were administered without evidence of untoward toxic effect.

4. A complete chart is kept showing blood pressure variations, pulse rate, respirations, temperature (rectal) every two hours, intake and output, the total dose of sodium amytal during the 24-hour period, comments regarding the patient's condition as judged by the attending nurses. It is necessary to keep close observation and nurses are instructed never to leave the patient alone. The physician must be available at all times and usually visits the patient 8 or 10 times daily.

5. The patient is kept in a darkened, quiet room with good ventilation but no drafts. All disagreeable stimuli, unnecessary noises, bright lights, audible conversations and other irritations are to be avoided. The patient must be kept lying on the side to avoid danger of swallowing the tongue or the accumulation of mucous in the pharynx. The patient is moved during the terminal phase of the narcosis to a bright, cheerful room and every effort is made to create an atmosphere of optimism and encouragement. Two thousand calories daily in the form of semi-solid or liquid diet are given. Twenty-five hundred cc. of fluid intake daily are required.

6. An emergency tray kept at all times in the patient's room is made up of the following: (a) mouth gag, (b) tongue forceps, (c) adrenalin 1:1000, (d) strychnine for hypodermic use, (e) picrotoxin (a specific antidote for amytal poisoning), (f) hypodermic syringe and needle, (g) 20 cc. syringe and intravenous needle, (h) small catheter to use as aspirator for dislodgment of mucous, (i) ephredrine sulph. gr. 3/4, strophanthin gr. 1/100; coramine; caff. sod. benzoate; digalen in ampoules and 50 per cent glucose ampoules.

7. The duration depends upon the patient's reaction to the treatment. This can be judged with fair accuracy during the semi-lucid intervals. The longest period of narcosis and the shortest accepted for report in this communication were 22 and 5 days respectively.

8. The nurse should write down all that the patient says. It is important for the physician to have a verbatim account because of

the value of the patient's uncensored remarks during the semi-somnolent periods. No effort is made at deep psychotherapy, the effort being to create a positive suggestion by means of encouraging statements, optimistic prognosis, etc.

COMPLICATIONS.

In our experience, complications have not been sufficient to produce any great alarm and are dealt with symptomatically. In a total of 115 prolonged narcosis treatments given, complications occurred in the following frequency: fever—15; mucous in throat—8; convulsions—8; retention of urine—6; aspiration—5; vomiting—4; excessively low blood pressure—4; cystitis—2; pulmonary complications—2; hiccough—2; disorders of breathing—2; swallowing of the tongue—1; cough—1; other cardiovascular complications (collapse, etc.)—1, and abdominal distention—1. We have not found evidences of severe acidosis or ketosis during the treatment in any case and we have seen no indication for using insulin and glucose. It is our belief that the fevers which have been reported by Parfitt [22] and others are due to infection rather than to the drug per se. In our experience, an adequate fluid intake has been sufficient to combat dehydration fevers. The appearance of fever in each instance we have been able to account for by infections, which can be found on careful examination. The convulsions are epileptiform in type and are preceded by a rather prolonged premonitory phase for several hours in which flightiness, apprehension, anxiety, fear, nervous twitching of the hands, coarse tremor of the lips, tongue and extremities and circumoral pallor are pronounced. These can be avoided by a slow reduction in the dose of sedative. We find no particular value in the convulsion itself although in several instances the attack has been followed by remarkable lucidity of several hours duration. Abnormal fall in blood pressure below 70 mms. of mercury systolic can become dangerous but is effectively combated by small doses of ephedrine sulphate, hypodermically, or benzedrine sulphate by mouth. In several instances vomiting has been overcome by giving the drug rectally. In our experience, it has been possible in many instances to carry through the full narcosis treatment even in the presence of a fair number of complicating factors.

Results.

In Table IV the criteria used are as follows:

Recovery means prompt remission of psychosis or discharge from the institution and continuing at the present time to maintain a social or occupational status considered normal. It means that, as far as could be determined, the recovery was directly dependent upon the therapeutic effort. Delayed recoveries are not included.

TABLE IV.

Permanent improvement means the ability to maintain a higher level of social adjustment from the cessation of treatment to date. In some instances it means advance from an acute to a convalescent ward or return home under somewhat modified environmental status.

Temporary improvement means apparent recovery or definite clinical improvement, of relatively short duration, 10 days to 90 days. It also implies a subsequent regression in many cases ultimately reaching a level approximately equal to the one existing before the treatment. A number of patients who showed this tem-

porary improvement went on to complete recovery after having relapsed temporarily.

Unimproved or *unchanged* designate those patients in whom no change for better or worse was apparent as the result of the treatment. In this group we included also a number of patients who ultimately recovered and were discharged but whose recoveries did not seem to be directly dependent upon the narcosis treatment.

DISCUSSION.

Physiological changes under the influence of sodium amytal have been studied by a number of investigators. Broder [17] reports on the hydrogen ion concentration, carbon dioxide content, cholesterol and non-protein nitrogen changes in 12 cases during and after sodium amytal treatment and concludes that the changes were too slight to justify any dogmatic statements. Dameshek, Loman and Myerson [23] studied the blood pressure and metabolic changes resulting from large and smaller doses of sodium amytal. They found a rather marked fall in systolic blood pressure, a somewhat lesser fall in diastolic blood pressure and a fall in temperature averaging 1.1 degrees Fahrenheit. They found that the Babinski did not become positive in any case. The pupils became constricted and the most striking finding was a marked and rapid fall in basal metabolism which fell from 7 to 70 per cent from its original level, the average being 26 per cent. The oxygen and dextrose " uptake " by the brain became definitely diminished. In a small group of patients who had received long continued thyroid medication and whose basal metabolism was considerably elevated, the drug produced an extreme drop, averaging 52 per cent. The authors believe that the extreme fall in metabolism is greater than can be explained by sleep alone and therefore must be due to either, (1) the particular type of sleep, or (2) a combined effect of sleep and the depression of certain brain centers. The speculation is that the profound effect is due to a depression of the hypothalamus with a resultant effect on both sleep and metabolism. Shapiro,[24] in 1937, published observations of oxygen consumption rate in psychotic patients who had been given sodium amytal. He observed a marked fall in oxygen consumption rate but feels that there is no correlation between it and the amount of sodium amytal given nor between it and the type of psychosis

treated. He suggests that the action of sodium amytal is on the hypothalamic portion of the mid-brain. Other theories as to the beneficial effects of the narcosis treatment are to the effect that the cellular rest, and time and opportunity afforded the cellular metabolism to store up reserve for subsequent expenditure, account for the clinical improvement.

Müller [25] believed that the effect was dependent upon central anesthesia with interruption of the vicious circle of affective agitation and motor agitation. He concluded that sleep and the interruption of disease functions, by means of tissue rest, constitute the chief therapeutic effect. Klaesi [6] made a comparison between the healing effect on inflammations by application of local anesthesia, and the soothing action of the hypnotic sleep on the disturbed brain of the psychotic. Hackfield [26] believes that the autonomic dysfunctions reflected in salivary secretion and gastric secretion, etc., make up part of a vicious circle in which the cerebrum becomes disturbed by reflex action and that the effect of the drug is rest resulting in a reduction of the afferent stimuli. The therapeutic attack in narcosis breaks the cycle either in the brain stem or cerebrum producing absolute rest.

The psychological effects have been reported upon in very illuminating manner by Bleuler,[27] Lindemann [28] and others. Lindemann reports that sodium amytal in normal persons furthers the friendly contact with the outside world and decreases self-absorption. Its most marked effect is shown in individuals suffering from schizophrenia who have withdrawn their interests from the outside world. Particularly increased contact and increased interests in the outside world resulting from sodium amytal were observed in schizophrenia. It is interesting that he finds that sodium amytal which restores outside contact also restores the normal level of coordination as determined by the chronaxia method (ratio). Conversely, he finds that a drug which facilitates withdrawal from the outside world also produces a regression in the pattern of neurophysiological responsiveness (mescaline and hashish).

There is no question but that sodium amytal, in the experience of all observers, has facilitated contact and has rendered the patient accessible to psychotherapeutic efforts of the physician. The rapport is phenomenally improved in every instance. Historical data

and factors not heretofore available from the patient himself are revealed during the induction phase and later in the course of the withdrawal of the drug. Broder [17] finds that patients under the influence of amytal are amenable to suggestion and are able to develop a better understanding of the psycho-dynamics of the illness. Horsley believes that not only is the censorship reduced but there is a hyper-acute memory which serves to further facilitate psychopathologic formulations. Horsley [15] is so enthusiastic that he believes that sodium amytal narcosis of superficial depth offers a practical substitution for the methods of psychoanalysis. Jelliffe [29] has expressed it admirably in the following terms: "Amytal does away with the censorship—the hyper-vigilant control of repression. The hyper-vigilant state of hostility has been abrogated by the drug. In these periods of release one can get at the dynamics of the psychosis. The drug analytic method offers a valuable extension of our capacities for getting at and understanding repressed, unconscious material."

The rôle of psychotherapy in accomplishing recovery or permanent improvement seems to be an established one. In our experience, no particularly deep psychotherapeutic efforts are necessary. The physician's constant presence in the picture, the reassurance of his constant attendance and the solicitude of the nurses, the strong, positive suggestion of direct nature such as optimistic statements, encouragement, reassurance of recovery, etc., seem to us to be of greater significance than any efforts at deeper techniques. The nurse's notes contain verbatim records of the productions of the patient and these are of great value in reviewing with the patient in his state of restored insight the dynamics of the illness. It has been stated by others that the depth of the narcosis seemed to have little effect on its therapeutic value. In our experience, this does not seem to hold true. In those cases in whom it was thought dangerous to administer the deep narcosis a modified narcosis method has been employed but the results are not as encouraging. Likewise, in cases in which the treatment has been interrupted because of the appearance of complications, the brief period of narcosis does not seem to have been particularly beneficial.

Sakel,[30] in his discussion of insulin treatment of schizophrenia, gives a theory regarding the effects of that therapy which may be

invoked in application to narcosis therapy. Sakel and his collaborators speak of the effect of insulin upon the psychosis " in inhibiting that which is functioning (the psychosis) and in activating that which is latent (the normality)." It seems that this theory in substance means that the psychosis can be regarded as a disorder superimposed upon and inhibiting normality. If the psychosis can be interrupted, normality may temporarily, at least, break through psychosis. If the restoration is complete enough, normal reactions may be sufficiently deeply intrenched to endure more or less permanently. It would seem that in narcosis therapy this interpretation might come very close to direct application and there can be little doubt that apparent suppression of the psychotic manifestations occurs and normality is temporarily activated. It is the fixation of this temporary normality, with the help of the physicians and nurses upon whom the patient is thrown into dependent relationship, which represents recovery. The assistance of direct and positive psychotherapy, the creation of an environment which is normal, and yet which is made more desirable than the psychotic situation, represents the potent forces in the psychological aspects of the treatment. A promotion, then, of readjustment in this somewhat softened, oversolicitous, but nonetheless, real environment is the keynote to the success of the narcosis therapy.

Summary.

1. From the studies in the past six years regarding the physiological reactions which occur under the influence of sodium amytal we can conclude that the following definite changes at the physiological level take place: (a) dilation of cerebral blood vessels, (b) lowered blood pressure, (c) marked lowering of oxygen consumption rate, (d) decrease of oxygen and dextrose " uptake " by the brain tissue, (e) a change from abnormal to normal in certain neuromuscular responses as measured by the chronaxia method. The conclusion seems to be that the drug acts upon the hypothalamus affecting the sleep and metabolic centers as well as upon the higher psychic functions.

2. On the psychological level the narcotic agent promotes contact, breaks through psychotic resistance, renders the patient more accessible to psychotherapeutic endeavors and seems to enable the

patient to reveal hidden sources of conflict which in the non-narcotic state are not available either to the patient or to the physician. It transports the depressed, the agitated and involutional melancholia patient into a calm serenity which offers him at least temporary relief from his torments. Many depressions express optimism (for the first time since the onset of illness) after the first few days of treatment. There appears to be some degree of neurophysiological readjustment paralleling, and possibly constructively influencing, the psychological changes.

3. There seems to be a general feeling among those who have used the narcosis method that results in schizophrenics are not altogether encouraging. Our results show approximately a 22 per cent recovery rate which cannot be overlooked. It is true that these results do not compare very favorably with the high percentage of recoveries reported by workers with the insulin treatment in schizophrenia. Nevertheless, in many instances it has been successful.

4. The more experience we accumulate in the management of patients under narcosis therapy, the less standardized the treatment becomes. We are less likely to be dogmatic about dosage and indications for changing the course of the treatment. There is a tendency to judge trends of improvement on a basis of day to day observation and to use modifications of the treatment especially in the involutional psychoses.

5. The method is not necessarily a physical hazard if patients are chosen with care. In fact, many patients show striking physical improvement in skin color and tone, disappearance of acneform eruptions, and in two instances a pre-existing colitis entirely disappeared. The complications have, in general, not been severe in our experience. There have been no fatalities and we can say with assurance that no discoverable systemic damage has been done. We have found no need for the administration of glucose and insulin inasmuch as under sodium amytal narcosis severe ketosis does not occur.

6. The greatest therapeutic usefulness of the narcosis method is apparently in the manic-depressive group, especially in the acute manic attack. Apropos of its usefulness in interrupting the course of a manic episode, the following case will be illuminating:

CASE 86.—College girl of 19. Father manic-depressive, circular. Suddenly developed overactivity, flight of ideas, distractibility. She was placed

in the college infirmary the first day of the illness, given sodium amytal at once, moved in semi-conscious state to hospital where narcosis was given. After first seven days emerged with marked manic symptoms. Narcosis was resumed for five days. The patient emerged remarkably improved and continued with rapid, uninterrupted gains. Returned to college and finished her junior year creditably with her class. In this instance the patient was spared the deteriorating experience of an attack of full blown acute mania; the nature of her illness was not known by fellow students. Remains well one year after discharge from the hospital.

7. The conclusions of some of the other physicians who have had experience with this technique are illuminating. Bond [31] has stated that narcosis should be tried in almost every case of acute mania. He believes that acute mania, if it goes full force and untrammeled represents a deteriorating experience which permanently damages the psychic resistance of the patient. The precipitation of the patient into a state of illness where intimate bedside nursing is imperative has a powerful psychological contribution to make to the other therapeutic mechanisms of the narcosis treatment. Strecker [32] believes that the results from the narcosis therapy are significant enough to justify its continuation as a standard method of treatment. He states, "In my experience, the patients particularly benefited were those in the acute manic phase of manic depressive psychoses but any of the manifestations of the manic phase seem to be favorable for treatment. In a number of other psychotic and neurotic states, the therapy seems to be helpful. For example, in the intense agitation of involutional melancholia a modification of deep narcosis therapy has been productive of surprisingly good results." Appel [33] states that the best results seem to be obtained in young, intelligent manics. It is also useful to tide over acute schizophrenic episodes and is of great practical use in many instances in that it obviates the necessity for commitment. It is also useful in relieving the agitation and tension in certain involutional psychoses.

DISCUSSION.

DR. FREDERICK L. PATRY (Albany, N. Y.).—Any method or procedure that improves upon nature's way of handling sickness should obviously be taken advantage of.

Drs. Palmer and Braceland merit our thanks for having focused our attention upon a type of therapy which has definitely proved its case. From a scientific point of view, one would wish that the authors present a control series of cases which respects the reaction type, age, sex, and other pertinent factors. On the other hand, the psychiatrist chiefly concerned with capitalizing treatment possibilities in every case may well point to the unenviable experience of untreated patients suffering from similar types of illness. For example, whereas the statistical average duration of untreated cases of manic-depressive psychosis is somewhat over four months, patients treated by the authors' method of narcosis therapy may recover within as short a period as two weeks, and the average is decidedly less than in untreated cases. The results in the schizophrenias are not so encouraging, but are not to be minimized, since recovery or permanent improvement is higher than the natural remission rate.

The advantages of narcosis therapy are manifold. The hazards are practically non-existent in the hands of well-trained personnel. The authors report no mortality, although a few fatalities are recorded by certain psychotherapists using other narcotics than sodium amytal, which is the drug of choice in this series. The narcosis method facilitates early treatment by making commitment unnecessary, and thus preventing so-called stigma. This latter regrettable factor would be enhanced if the patient were required to stay out of social and occupational circulation the usual time required for readjustment without narcosis therapy. Obviously, this form of therapy is advantageous in several ways: it promotes the patient's comfort and hopefulness; it is a measure of economy with respect to both duration and cost of treatment; it facilitates the handling of patients and simplifies the work of hospital personnel; it eliminates the factor of destructiveness and aggressiveness.

Of cardinal importance is the prevention of possible regression which might lead to deterioration. From the research and psychotherapeutic point of view, narcosis therapy unmasks the patient's biological functions, improves rapport and enhances the benefits of suggestion.

I should like to ask the authors if they have any data relative to treated and untreated recurrent psychotic reaction types. Also, the significance of the time factor from the onset of the present illness to the institution of treatment; thirdly, although the period of critical observation and comparison of narcosis treatment versus insulin treatment of schizophrenias is insignificant for comprehensive evaluation, I am wondering how the authors feel about this question.

DR. MARY G. SCHROEDER (Elgin, Ill.).—I am reporting two series of cases from the Elgin State Hospital. They were not so extensive as those reported

by Dr. Palmer and Dr. Braceland, consisting only of 13 cases in the first series, and 19 in the second. I am also very sorry to report that they were not so successful.

The first series of 13 cases was conducted by Dr. Magnus, of Chicago, Dr. Read and Dr. Nennancy of the State Hospital of Elgin. They were carefully selected, patients with cardiorenal or lung conditions or liver difficulties were excluded. Written permission from the responsible relative was secured in each case to protect the hospital from any difficulties. Both of these series are reported in the collected papers from the Elgin State Hospital.

Dial was used in the first series, in a modification of the Burg-Helsey method, that is 400 c. c. of a physiological salt solution was given daily by rectum, after the narcosis was established. In three of these doses of 400 c. c. each, some 60 grains of dextrose were included. The dial also was included in this salt solution, which was given by rectum, according to the Mercury-drip method. With these cases were also included 25 patients that had been treated by Dr. Magnus in Chicago. I am unable to give you the exact data of those treated at Elgin. There were 18 schizophrenias, 10 of which were catatonic, 5 manics, 3 depressives, 4 involutionals and 3 undiagnosed. Improvement was shown in 60 per cent of the manics, 50 per cent of the depressives, 40 per cent of the catatonic, and in two-thirds of the hysterics. Of the neurasthenics, 100 per cent recovered. Unfortunately, there were two deaths, one dementia præcox, and one undiagnosed psychosis.

Conclusion of the authors: sustained sleep therapy is a valuable method in manic-depressive psychosis and certain types of schizophrenia and in the psychoneuroses.

The second series was conducted by Dr. Schiller of the Elgin State Hospital, and followed very closely the method of Dr. Palmer. Fifteen grains of sodium amytal were given to induce narcosis, followed by oral feedings daily for 10 to 14 days. The patients received 3000 calories daily, and 3000 c. c. of fluid. Nineteen patients, 14 of whom were women, were given this treatment. They included 10 schizoids, one of whom recovered, and two improved; 9 manics, two of whom recovered, two improved and one died; therefore, 15.7 per cent of the manics recovered and 21 per cent improved.

Our results were not as favorable as those reported by others, perhaps because our patients were deteriorated and had been so for a long time. Because of this, more drastic methods of treatment are being carried on at Elgin now. Eight recent schizophrenics have been treated by the insulin shock method. Six of these have been paroled and have shown their previous or higher than previous level of accomplishment. One has shown no improvement. The five older cases had been sick from three to thirteen years, and only one of them has improved.

Then there is also a very interesting experiment with metrazol which is going on at present; the water soluble camphor is given intravenously in 10 per cent solution. It is begun with 1 c. c. and continued to 7 c. c., the injections being given three to four days apart. Nine cases, all old dementia præcoxes,

PROPERTY OF PSYCHIATRIC INSTITUTE

are being treated. One not quite so old has been paroled after only five injections. Four cases are markedly improved, and one is ready to go home. This method shows therefore 66 per cent improvement.

Another form of treatment is that of sulphur-in-oil injections intramuscularly for the schizophrenics and for those who show chronic excitement, even the older cases, also the inaccessible, indifferent and confusional types.

A report is also included in the collected papers by Dr. Shapiro and Dr. Read of 176 newly admitted cases, contrasted with 176 admitted in 1930 who did not have this treatment. Thirteen of those treated showed remissions, whereas only three of the untreated cases in the 1930 series showed remissions; six showed marked improvement, compared with fourteen in the untreated series; twenty-four, improvement, but with relapse, as against six in the untreated group; amelioration in twenty-three, and only fifteen in the untreated; twenty-eight, amelioration with relapse, and six in the untreated.

There were no changes in 80 of these 176 patients treated with sulphur-in-oil compared with 132 in those that were untreated in 1930; therefore, 45 per cent of the 176 cases in the treated group showed no change. We are convinced of its value in chronic cases of excitement, destructive, combative tendency and filthy behavior, where any amelioration of obnoxious tendencies is so gratifying both to the hospital and to the relatives.

Dr. W. L. Moore (St. Louis, Mo.).—I would like to ask Dr. Palmer if he institutes treatment by the intravenous method, and then carries it on by rectal.

Dr. Harry A. Schneider (Coldwater, Mich.).—I should like to ask if he discontinues treatment when the patient starts to show any unfavorable symptoms, particularly rise in temperature and abnormal lowering of the blood pressure below 90 systolic.

Dr. Julius Steinfeldt (Peoria, Ill.).—Does he have an emergency outfit? and I would like to know something about the fatality rate of his material.

Dr. Harold D. Palmer (closing) (Philadelphia, Pa.).—Dr. Patry mentioned one thing which I think ought to be emphasized, that is, that it is not uncommon to carry out successfully the narcosis treatment in a case of acute mania in a general hospital.

He asks first, dc we have any data on the time factor in treated or untreated recurrent disorders. I can only say this, that in one patient who had had two manic episodes before he undertook narcosis treatment, the average without treatment had been seven months. He has had three episodes since that time, each treated with the narcosis therapy, and the average duration from admission to discharge is six weeks.

With regard to the time from onset of symptoms to the beginning of the narcosis treatment: we have not attempted to determine this figure exactly, but it is rarely longer than two weeks, and in one instance, which I had hoped to cite, was one day.

As to whether or not narcosis has much to offer in schizophrenia, I believe that we have distinctly less to offer than the insulin treatment as it is being done in this country today.

Our results so far with the narcosis treatment compare rather unfavorably with our results so far with the insulin treatment in schizophrenics. However, I wish to call attention to the fact that we have about 22 per cent recoveries in the schizophrenics treated with insulin.

Dr. Moore has asked if we ever used the intravenous method for induction of a prolonged narcosis therapy. We have discarded intravenous altogether, because it is unnecessarily hazardous. The only severe complication we had was a cardiovascular collapse, necessitating intravenous adrenalin and artificial respiration; it was a case in which sodium amytal had been very carefully given intravenously. We induce the sleep by oral doses, or where we don't get sufficient cooperation, by some restraint and rectal administration.

Dr. Schneider asks if we continue in the face of certain complications. Yes, we continue with temperature rises as high as 101 or 102, if the rise in temperature cannot be attributed directly to some organic or some infectious focus. Not uncommonly we ride through a rather high fever by giving symptomatic treatment. As to falls in blood pressure below 90, we very commonly carry on through falls of blood pressure with a systolic going as low as 70. We have found ephedrine sulphate given hypodermically to be almost specific in dealing with this fall in blood pressure due to the barbital sedatives.

Time did not permit me to give the description of the outfit in the discussion of technic. However, it consists of tongue forceps, mouth gag, adrenalin solution, strychnine solutions, picrotoxin, a hypodermic syringe and needles, a 20 c. c. syringe for administration of intravenous glucose if we feel it necessary, a nasal catheter for use if respiratory blocking occurs, and we have ampules of strophanthus, coramin, digitan, calcium benzoate, ephedrine sulphate—in other words, a tray which might be at the bedside in any general anesthetic administration.

HYPERTHYROIDISM AND PERSONALITY.*

By WARREN T. BROWN, M. D., and EDWIN F. GILDEA, M. D.,
New Haven, Conn.

Physicians working with hyperthyroid patients have increasingly stressed the importance of the frequency with which such patients have experienced some emotional shock or strain just prior to the recognized onset of the illness. With varying emphasis, the rôle of such emotional shock or strain has been discussed as to the etiology or as to the precipitation of the clinical pictures of hyperthyroidism.

We shall consider the significance of the particular emotional shock or strain in the total life process of each of 15 individuals who have developed hyperthyroidism. Why have the experiences reported caused emotional shock or strain in these particular individuals? Kahn and Cohen [1] have postulated that "each individual brings into the world *his* capacity to experience, and each individual differs from every other individual in that all his capacities, necessarily including his capacity to experience, have been derived fundamentally from the biological potentialities which he has inherited from his progenitors," and "that one can deal with experience and the way of experiencing as springing from the biological makeup of the individual." We consider emotional experiences as definitely based on biological processes related to the nervous and endocrine systems. This implies that the endocrine system, and within it the thyroid gland, is instrumental in determining the individual's capacity to experience and consequently his way of experiencing.

Whenever thyroid pathology occurs it is observed that the behavior of the individual, that is his experiential expressions, are more or less changed. This is what seems to happen: emotional factors precipitate a thyroid imbalance with a change of behavior

* Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

From the Department of Psychiatry and Mental Hygiene, Yale University, School of Medicine, New Haven, Conn.

or experiential expression. The question is: is this biological and experiential change brought on as something perfectly new in the individual, or was there any sort of susceptibility or readiness in the individual biologically to react and experientially to express himself in this manner?

With this question in mind, 15 patients have been studied and the data analyzed in the following manner.

Observations.

Family History.—The family history of each patient was investigated in an attempt to find evidence of nervous instability in the parents or siblings.

Case 1.—The mother was nervous, hyperactive, energetic, excitable and easily worried. The father died of suicide attributed to an unhappy second marriage. A daughter is extremely "nervous," and because of this, is a source of worry to the patient.

Case 2.—The father was extremely irritable and excitable. The mother is excitable with definite mood swings. Two sisters are both hyperexcitable and exhibit enormous amounts of drive. The examiners have noticed that one sister demonstrates a definite bulging of the eyes when she becomes excited.

Case 3.—The mother was extremely excitable and irritable. Her excitability was extreme and through it she met her death when upon hearing a fire alarm she became terrorized, tried to run, slipped and fell downstairs, receiving fatal injuries.

Case 4.—No notable findings in the family history.

Case 5.—The mother was always excitable and showed a tendency to worry enormously. When her son entered the army during the World War she became extremely depressed and worried and showed the complete picture of a depression. She became worse gradually, although her son was never in real danger. She died on Armistice Day.

Case 6.—One sister died in diabetic coma. She was not known to be ill until she was found in the coma. One sister died of some advanced gastric disturbance. She was not known to be ill until the terminal stage of the illness was reached.

Case 7.—The mother was excitable and had cardiac hypertension for many years.

Case 8.—The father was nervous and restless and had frequent headaches. The mother died after several cerebral accidents. Although she was excitable and emotional, she never complained and while she was dying she ordered her children not to cry. One sister has had occasional "nervous breakdowns."

CASE 9.—The father recently had a leg amputation resulting from endarteritis. The mother had what is referred to as "shaking sickness" for the last five years of her life.

CASE 10.—No notable findings in the case history.

CASE 11.—The mother is a small nervous person who was always over anxious and very excitable.

CASE 12.—Most members of this family are irritable and excitable.

CASE 13.—The father was a sensitive, irritable alcoholic. A brother is sensitive, irritable and easily excited.

CASE 14.—Both parents were sensitive and unstable. The father committed suicide.

CASE 15.—The father dominated his family by constantly complaining of his stomach trouble. This same method of domination is now directed toward the patient.

NOTE.—All but two of our cases yielded evidence of a strong familial tendency toward nervous instability.

General Personality Traits.—Each patient's pattern of response to ordinary life problems is briefly summarized.

CASE 1.—Generally tense with a strong sense of responsibility, a sense of insecurity and a tendency to accept conflicts and difficulties as routine without complaint.

CASE 2.—Felt responsibility keenly, was extremely sensitive; he never admitted insecurity but constantly fought it.

CASE 3.—Generally anxious, insecure, easily frightened and tense. Constantly directed her energy toward gaining security. Never complained but accepted difficulties as routine.

CASE 4.—Generally anxious, but never complained. He had a strong feeling of responsibility and insecurity. He has put up a constant fight against insecurity.

CASE 5.—Generally anxious with fear of insecurity, but never complained. Actively fought difficulties which threatened her security.

CASE 6.—Generally anxious and tense with a marked fear of insecurity. He was easily disturbed emotionally, but declared he took things as they came.

CASE 7.—Constantly tense and anxious and for many years under a strain, but never admitted feeling anxiety or stress until she talked to the examiner.

CASE 8.—Responded to prolonged mental stress by bearing it in silence for a period of 34 years.

CASE 9.—Generally tense, anxious and obviously insecure, but says, "I leave well enough alone; I don't complain."

CASE 10.—A tense, anxious person with a strong sense of responsibility who never mentioned worries or fears to others.

CASE 11.—Generally apprehensive and fearful of death. Insecure and easily worried. Cried easily, but never in the presence of others.

CASE 12.—Strongly attached to his mother, he showed a marked need for approval. Assumed much responsibility as a salesman, but showed constant fear of disapproval. Never admitted any symptoms until they were thoroughly severe.

CASE 13.—Generally an active, energetic person who faced a very difficult situation without recognizing that it might be unusual. Struggled hard against insecurity.

CASE 14.—Generally immature and insecure. A jealous rival with her sister for her father's affection. Displayed a definite need for approval and attention. Had a strong sense of responsibility which led her to support a parasitic husband, even during her illness.

CASE 15.—Generally insecure and afraid of disapproval. She showed a marked sense of guilt and a strong sense of duty. Accepted many difficulties as routine and did not complain.

NOTE.—In their premorbid lives these people tend to *suffer in silence.* They combine an extreme feeling of personal insecurity with a strong sense of responsibility. Frequently they attach themselves to someone (a parent or parent surrogate) upon whom they depend for guidance and protection. Psychic trauma finds no outward expression, but is turned within. Similar traits in hyperthyroid patients have been observed by Agnes Conrad.[2]

Premorbid Psychopathic, Endocrine and Autonomic Nervous System Disturbances.—The majority of our patients show evidence of having had psychopathic, endocrine or autonomic nervous system disorders long before the hyperthyroidism developed.

CASE 1.—Fainting attacks at 14. Sweating of palms in response to emotional disturbance all her life. Has never been able to dance because it made her dizzy. Circumscribed period of depression at 28, duration three months. A second milder circumscribed depression at 40, duration two years.

CASE 2.—Tremor and bulging of the eyes in response to emotional stress in early life. Glycosuria. Chronically hypomanic.

CASE 3.—Sweating of the palms and soles of the feet in response to emotional disturbance since childhood. Frequent spells of blueness all her life ranging in duration from a few days to a few weeks, with one or two such spells lasting for periods of about two years each.

CASE 4.—Past history negative in this respect.

CASE 5.—Intermittent fainting spells, sweating of the palms, soles of the feet and the middle of the back in response to emotional disturbance.

CASE 6.—Sweating of the palms and soles of the feet all of her life in response to emotional disturbance.

CASE 7.—Nervous, anxious and excitable as a child.

CASE 8.—Profuse sweating of the palms and soles of the feet in response to emotional stress since childhood. Also flushing of the face and tachycardia. Excessively fearful, to a degree that she will not sit with her back to a door for fear that someone will come in when she isn't looking. Had several "nervous breakdowns," the first about one year after her marriage.

CASE 9.—Past history negative in this respect.

CASE 10.—Past history negative in this respect.

CASE 11.—Marked fear of dying associated with depresson at various periods throughout life. Has experienced this particularly during pregnancies.

CASE 12.—After multitudinous sexual activities with women of questionable character became engaged to a "good woman," and thereafter developed sexual impotence, necessitating postponement of the marriage.

CASE 13.—Unusually overactive and sensitive.

CASE 14.—A definite period of depression in 1924, at the age of 22, and a definite manic episode in 1932.

CASE 15.—Past history negative in this respect.

NOTE.—The vulnerability of these patients to emotional and vegetative nervous system disorders is frequently manifested symptomatically before hyperthyroidism develops.

Onset of Illness.—Comparisons are made in each case of the date of the recognized onset of the symptoms of hyperthyroidism and the date on which the patient was first seen by a physician.

CASE 1.—Onset 1924—restlessness, gastric symptoms, fatigue, tremor and hyperexcitability. Consulted a doctor in 1928.

CASE 2.—Onset 1932—irritability, fatigability and restlessness. Consulted a doctor in regard to insurance in 1935.

CASE 3.—Onset in 1935 with fatigue, nervousness, irritability and profuse sweating. Consulted a physician one year later.

CASE 4.—Onset in 1931 with nervousness, fatigability and weakness. Consulted a doctor in 1936.

CASE 5.—Onset in 1930 with sweating, blushing, shaking and loss of weight. Consulted a doctor in 1935.

CASE 6.—Onset in 1934. Family noticed nervousness, restlessness and irritability and loss of weight. Because of a spell of vomiting, she was brought by her family to a doctor in 1936.

CASE 7.—Onset in 1935 with sweating, flushing, tachycardia, weakness and spells of vomiting. Consulted a doctor a year later.

CASE 8.—Onset in 1897. Noticed swelling in the neck following a nervous breakdown. Treated by quack methods such as electrical treatments, chiropractic, etc., at intervals until she came to a doctor in 1935.

CASE 9.—Onset in 1935 with tachycardia, nervousness, dyspnea and weakness. Consulted a doctor four months later in 1936.

CASE 10.—Onset in 1923. Noticed weakness, nervousness and tremor and went for a trip with poor results. She was brought to the hospital because of bromide intoxication in 1934.

CASE 11.—Onset in 1933 with sleeplessness, irritability, tremor, and nervousness. Consulted a doctor in 1935.

CASE 12.—Onset in 1934 with restlessness, irritability and loss of weight. Entered hospital in 1935, one year later.

CASE 13.—Onset in 1935 with palpitation, dyspnea on exertion, precordial pain, tremor and weakness. Consulted a doctor about a year later.

CASE 14.—Onset in 1935 when the patient noticed weakness, loss of weight, general malaise. At that time she went to a physician complaining of a pain in the lower right abdomen; appendicitis was diagnosed and an appendectomy done. Hyperthyroidism was diagnosed in 1936. The patient, however, would not recognize the necessity for treatment until 1937.

CASE 15.—Onset in 1928, a lump in her neck was first noticed. She felt tired and weak, had some tremor and went to a physician at the time because she noticed small lumps in her breasts. The physician attributed the difficulty to pus in the tonsils. Hyperthyroidism was diagnosed in 1931.

NOTE.—With few exceptions these patients have persisted in attempting to fulfill their responsibilities in the face of the taxing symptoms of hyperthyroidism. Their first visit to a doctor has frequently been for secondary reasons such as to have a boil lanced or for an insurance examination. Some

of them have come only after the vigorous urging of their family or friends. Others consented to see the doctor only after they were totally incapacitated. In most cases the actual onset of the gross symptomatology has occurred more than a year before the doctor has been consulted.

Precipitating Situations.—In each of these cases there has been a definite disturbing situation experienced by the patient just prior to the recognized onset of hyperthyroidism.

CASE 1.—A combination of the loss of her son, her husband's bankruptcy and a controversy over her daughter's unhappy marriage.

CASE 2.—An unbearable partnership in business about which he remarked, "He has me in prison; how am I going to get out?"

CASE 3.—Loss of life's savings and constant unemployment of both the patient and her husband.

CASE 4.—An open fight with his two brothers followed by financial stress and unemployment which came one month after assuming the responsibility of marriage.

CASE 5.—The husband's unemployment followed by extreme financial stress.

CASE 6.—The death of a favorite sister and the responsibility for that sister's children.

CASE 7.—An increasingly difficult marital situation becoming unbearable in the light of the patient's increasing age.

CASE 8.—A termination of a prolonged intolerable marriage by divorce which instead of relief produced feelings of insecurity and guilt.

CASE 9.—The death of her mother and more recently her father's leg amputation.

CASE 10.—The loss of her husband followed by a losing struggle to earn a living during the business depression.

CASE 11.—Financial strain, her husband a chronic invalid and a daughter who is too "nervous" to work.

CASE 12.—After becoming engaged the patient became sexually impotent and put off the marriage many times. Illness developed during this period of uncertainty.

CASE 13.—A prolonged strain wherein the patient attempted to fulfill the demands of an unsympathetic husband who was sexually incompatible and chronically alcoholic. This during a period of financial stress.

CASE 14.—An incompatible marriage which left her forced to support a parasitic husband and a child on the inadequate income of a librarian.

CASE 15.—The recent and severe illness of a daughter and the recently assumed responsibility for the care and maintenance of both of her parents who were constantly quarreling between themselves.

NOTE.—In each instance the precipitating situation has represented a threat to the patient's security, either by loss of guidance and protection, or increased responsibility.

Pathological Reports.—Pathological reports of the resected gland material were obtained on all operative cases. On the two unoperated cases a description of the palpable gland was recorded.

CASE 1.—Hyperplasia of the thyroid gland.

CASE 2.—Hyperplasia of the thyroid gland.

CASE 3.—Hyperplasia of the thyroid gland.

CASE 4.—Hyperplasia of the thyroid gland.

CASE 5.—Hyperplasia of the thyroid gland, (slight) colloid adenoma.

CASE 6.—Hyperplasia of the thyroid gland.

CASE 7.—Diffuse hyperplasia of the thyroid.

CASE 8.—Adenoma of the thyroid.

CASE 9.—Hyperplasia of the thyroid, and hyperplasia of lymph node.

CASE 10.—Hyperplasia of the thyroid.

CASE 11.—Hyperplasia of the thyroid.

CASE 12.—Hyperplasia of the thyroid.

CASE 13.—Unoperated. Gland was enlarged, smooth and soft. The symptoms responded to iodine therapy.

CASE 14.—Hyperplasia of the thyroid.

CASE 15.—Unoperated. The gland was enlarged, smooth, soft and not nodular. The symptoms had responded to radiation of the thyroid repeatedly.

NOTE.—Of the 13 pathological reports, 12 were hyperplasia of the thyroid gland, and one (8) was adenoma of the thyroid. In the two (13 and 15) unoperated cases the gland was definitely palpable, soft and smooth, and gave the clinical impression of hyperplasia. One of these (13) responded readily to iodine therapy, and the other (15) had yielded symptomatically to radiation of the gland several times before coming to our clinic.

Postoperative Course.—All of these patients are still being followed by one or more departments of the New Haven Hospital.

CASE 1.—This patient had a recurrence of hyperplasia of the thyroid two years after the first operation and shortly following a new emotional disturbance. At present, about 18 months after the second operation, she is again in a stressful situation and is experiencing recurrence of symptoms.

CASE 2.—The patient had a recurrence of symptoms followed by a manic attack and hospitalization. Following the operation he returned to the original stressful situation.

CASE 3.—The patient had some immediate relief, but most of the symptoms are retained and recently have become progressively worse. She returned to an unchanged stressful situation.

CASE 4.—After nine months the patient is apparently symptom free. Since operation he has been under no particular strain.

CASE 5.—Symptom free for eight months, but began to develop headaches similar to those experienced preoperatively about two months ago. The patient is still under strain.

CASE 6.—When seen about four months after operation the patient was still experiencing weakness and fatigability, but was improving. She was under no particular strain and had been free from sources of worry since the operation.

CASE 7.—After six months there was some improvement; the patient is still tense, anxious and weak. She is still under emotional strain with her original situation unchanged.

CASE 8.—Remarkable symptom relief after operation followed by a definite recurrence of all symptoms after the patient became involved in a difficult court litigation.

CASE 9.—Complains of feeling cold, shows a low B. M. R. of about −16 and a marked exophthalmos in the right eye only.

CASE 10.—After one year the patient still experiences marked tachycardia and weakness.

CASE 11.—After two months patient was greatly improved, although still weak and easily fatigued.

CASE 12.—Showed no exophthalmos before the operation, but developed a marked postoperative exophthalmos.

CASE 13.—Not operated. This patient has been readmitted to the hospital, and any attempt to relieve or alter her stressful situation has failed. It is noted that when she leaves that situation and enters the hospital her symptoms are relieved and her B. M. R. goes down.

CASE 14.—The patient is still overactive and irritable, but still shows weakness. She has returned to the original stressful situation.

CASE 15.—Not operated, but relieved by radiation after which she was symptom free until the death of her mother when the symptoms recurred in full and were again controlled by radiation at intervals for about three years. She is at present hospitalized because of a bizarre psychosis including symptoms of tension and anxiety.

NOTE.—It is apparent that with whatever success treatment is directed toward the thyroid gland, the fundamental way of experiencing of the patient is not altered. If, after treatment, the patient returns to the same or a new stressful situation or experiences further shock, recurrence of the whole picture of hyperthyroidism is likely. Relief from stress and strain is essential to continued recovery.

Our patients have four points in common: first, a constitutional predisposition to hyperthyroidism; second, a way of experiencing which involves a peculiar susceptibility to emotional shock or strain; third, a severe disturbance in the form of a sudden shock, or a prolonged strain, or both, prior to the recognized onset of their illness; the fourth is hyperplasia of the thyroid.

DISCUSSION.

CONSTITUTIONAL PREDISPOSITION.

With Warthin [3] we contend that the potential predisposition to hyperthyroidism is present in the individual at birth, and that it is constitutional in nature. Various metabolic and nervous disorders may be discovered in the families of these patients. Thyroid disorders, diabetes, cardiac hypertension, general nervous instability, and evidence of manic depressive psychosis are among the most common. Such evidence strongly indicates the importance of the hereditary factor in the production of this constitutional group.

In general our patients have soft thin skin, rounded and soft body tissues, abundant hair, and youthful figures. These features are among the "chief morphologic stigmata" of Warthin's "Grave's Constitution." These people showed a marked tendency to blush under the observation of the examiner, and most of them were unconscious of it. At times, when patients were asked if they blushed easily, their faces would rapidly redden while they, in all sincerity, stated that they had never blushed in their lives. Un-

consciousness of gross signs of lability of the autonomic nervous system probably explains the difficulty in eliciting evidence of nervous instability from the premorbid histories of some hyperthyroid patients.

Hyman and Kessel [4] and others contend that hyperplasia of the thyroid is secondary to and symptomatic of autonomic imbalance. Our findings suggest that a labile autonomic nervous system is involved in the constitutional predisposition to hyperthyroidism. This suggestion is supported by the fact that in some of our patients such symptoms of hyperthyroidism as sweating and tachycardia, which are vagosympathetic in origin, are exaggerations of disorders already present before the onset of the disease, and do not always disappear after thyroidectomy.

While the thyroid gland is admittedly not solely responsible for the production of hyperthyroidism, it is highly improbable that it is an innocent bystander. The fact that when hyperplasia occurs many symptoms are exaggerations of premorbid behavior, and that subtotal thyroidectomy subdues these symptoms which recur with further hyperplasia, is incriminating. Regarding the development of some of the characteristics of exophthalmic goiter, Boothby [5] has suggested that they " may be secondary to a peculiar irritation or some stimulation of the vagosympathetic system "; and " that the origin of this sympathetico-stimulating substance is in the thyroid is indicated in man by the fact that partial thyroidectomy, even without the administration of iodine either abolishes or decreases in the large majority of instances the intensity of the characteristic symptoms of exophthalmic goiter attributable to this substance." W. O. Thompson [6] has pointed out that " the peculiar nervous manifestations of exophthalmic goiter appear to be satisfactorily explained as exaggerations of the customary reactions of the patients who are usually of the emotionally unstable type." Our data support his conclusions, but we further maintain that the prehyperplastic thyroid gland influences the " emotionally unstable " way of experiencing of the premorbid person in the same direction, if to a lesser degree, as does the hyperplastic thyroid influence the " peculiar nervous manifestations " of the person with hyperthyroidism. A sensitive thyroid gland which is susceptible to hyperplasia figures in the premorbid constitution.

THE WAY OF EXPERIENCING.

The biological makeup of individuals with the constitutional predisposition to hyperthyroidism is fundamental in the production of a characteristic way of experiencing. The outstanding common features in all these personalities are: an extreme feeling of personal insecurity, a strong sense of responsibility, and a tendency to suffer in silence. The feeling of insecurity leads them to seek sources of protection. This accounts for the fact that some of them maintain prolonged attachments to parents, or attach themselves to other personal protectors. They also value highly such sources of ego security as their savings or their jobs. The sense of responsibility is probably born of their directing their energy toward protecting, maintaining or pleasing their sources of ego security. Agnes Conrad [2] has mentioned, in this respect, the need for the approval of the parent. It may well be a fear of disapproval which prevents their complaining and leads to the tendency to suffer in silence. This feature is seen in its advanced form in some of our patients who persist in fulfilling their responsibilities without complaint for long periods after the onset of clinical hyperthyroidism.

Any threat to the security of such persons is experienced by them as an emotional shock or strain. In spite of the lack of complaint, we see evidences of the effect of this emotional trauma in the premorbid lives of some of our patients who have apparently manifested susceptibility to other conditions before the development of hyperthyroidism. Personalities constitutionally predestined to the way of experiencing common to these patients are naturally vulnerable to manifestations of any predispositions to nervous or endocrine disorders they may possess.

PRECIPITATING SITUATION.

It is not an incident but the way an individual experiences an incident that produces emotional shock or strain. Some persons may meet or constantly deal with problems which threaten or actually damage their personal security with little or no emotional disturbance. Not so our patients who with their innate feelings of insecurity experience any threat or damage to their security as a definite emotional trauma. Some insecure persons, it is true, may

experience threats to their security with emotional trauma and show no resulting damage to their endocrine systems. Some of these find outward expression for their emotions. Some turn them within with resulting damage to other more labile parts such as the gastro-intestinal or cardiovascular systems.

It is our contention that in the patients studied the development of hyperthyroidism has not been due to the operation of only one or some of the components of the pre-hyperthyroid personality. It is a result of the interaction of the total combination. This interaction is set in motion by situations encountered by these personalities and experienced in their way. In each instance the precipitating situation has represented a threat or damage to the patient's personal security.

COMMENT.

While this combination is certainly not offered as a universal etiology for hyperthyroidism, our data indicate that some cases develop in this manner. The constitutional susceptibility must naturally vary in degree in different individuals, some requiring greater stimuli to set them in motion than others. The individual's susceptibility doubtless fluctuates in response to such factors as the general physical status and the amount of available iodine.

The study of the premorbid histories of these patients reveals many common personality traits. In the future the recognition of such traits in other persons should lead to the suspicion that they might fall into the hyperthyroid susceptible group. Once the susceptibility is discovered effective prophylaxis may be applied.

CONCLUSIONS.

1. There is a constitutional predisposition to hyperthyroidism implicating a sensitive thyroid gland.

2. The way of experiencing of persons constitutionally so predisposed involves: (1) an extreme feeling of personal insecurity; (2) a strong sense of responsibility; and (3) a tendency to turn the effects of emotional experiences within rather than give them outward expression.

3. Any threat to the security of persons with this constitution and way of experiencing may produce a serious emotional disturbance.

4. Prolonged emotional strain, severe emotional shock or a combination of the two may precipitate hyperplasia of the thyroid gland in these personalities.

5. Certain personality features of this constitutional type are sufficiently similar to give definite clues for the recognition of persons possessing a predisposition to hyperthyroidism before the clinical picture of the disease develops.

DISCUSSION.

DR. FRED P. CURRIER (Grand Rapids, Mich.).—One deems it a privilege to discuss this paper by Dr. Brown and Dr. Gildea. To those of us who have spent our medical lives in one of the important goiter regions, a paper which contributes either to the therapeusis or prevention of hyperthyroidism is of special interest.

As a fundamental groundwork, the authors quote Kahn and Cohen, as follows: "Each individual brings into the world his capacity to experience and each individual differs from every other individual in that all his capacities, necessarily including his capacity to experience, have been derived fundamentally from the biological potentialities which he has inherited from his progenitors."

One must ask himself if one's capacity to experience does not connote quantity and if so, is it not logical to ask how are we to measure this capacity which one brings into the world and which from the very beginning is impressionable.

We are presented with the family histories of 15 cases, all but 2 of which showed strong familial tendency toward nervous instability, but in these family histories we note that there is not one case of actual hyperthyroidism.

The authors state that various metabolic and nervous disorders, such as diabetes, hypertension, cardiac disorders, discovered in the family histories of these patients, constitute evidence of the importance of the hereditary factor in the production of this constitutional group. If such be the case, wherein are we justified in associating the findings specifically with thyroid disease?

We are later told that W. O. Thompson has pointed out that the peculiar manifestations of exophthalmic goiter appear to be satisfactorily explained as exaggerations of the customary reactions of the patients who are usually of the emotionally unstable type. The authors state: "Our data support his conclusions but we further maintain that the pre-hyperplastic thyroid gland influences the 'emotionally unstable' way of experiencing of the premorbid person in the same direction, if to a lesser degree, as does the hyperplastic thyroid influence the peculiar nervous manifestations of the person with hyperthyroidism."

Such a statement challenges one's curiosity and we would be pleased to know what chemical or microscopic evidence there is to support it. Boyd, the pathologist, states that during life the thyroid is continually being acted on by stimuli of various kinds, chemical, bacterial and psychic, which tend to induce hyperplasia.

We also know that there are certain nuclear groups in the hypothalamus which are closely associated with all the symptoms of exophthalmic goiter. Still we do not know the real cause of hyperthyroidism. We do know that removal of part of the gland may alleviate the symptoms. Is it not reasonable to suppose then that even the term "hyperthyroidism" may be an improper one for the disease?

This paper has brought to our attention some of the important signs and symptoms in cases of potential hyperthyroidism and in doing so suggests a method of attack useful in prevention.

Dr. Eugen Kahn (New Haven, Conn.).—Dr. Currier has said that the real cause of hyperthyroidism is not known, and we agree with him. We have not maintained that the real cause of hyperthyroidism has been found. What Drs. Brown and Gildea tried to do with this group of patients and what they are now doing with another group of patients with other clinical manifestations is this: They look over the personality and the history as far as they can get hold of them, always asking themselves the question, "What kind of people are these?"

We are of the impression that in this series of 15 cases, which were not selected but just taken, as far as I know, at random as they came to the medical clinic and wards, definite trends were found that these people had in common. Nobody would say today all hyperthyroid patients belong to this kind of personality, but these people obviously do.

There are three points I would like to allude to briefly. I have the impression in this group of patients that there is a definite physical disorder, namely, the hyperthyroidism; that there are emotions that certainly play a rôle—there is always a situation tied up, of course, with these emotions; then there are the therapeutic problems, what to do eventually as to prevention of this disease. In this connection there is one thing I would like to stress. We sometimes feel that in some places our internists and our surgeons may not be very accessible to psychiatric cooperation. In our own center we are fortunate in this respect. I do think that the psychiatric contribution would in many instances be useful to the surgeon and to the internist in a better understanding of these patients and as a result one might not infrequently save a patient his thyroid.

Dr. William L. Nelson (St. Louis, Mo.).—It is not a long throwback to the time that I graduated in medicine. At that time, hyperthyroidism was looked upon as an involvement of the thyroid gland *per se*. As a student, I accepted this view of our teachers, but as I thought of thyroid conditions and began to be interested in mental and emotional states, I began to appreciate the make-up of some of these people prior to the time that they developed their hyperthyroid state; and when I say hyperthyroid state I refer to the non-adenomatous character of thyroidism. Surgeons continued to operate on the basis that it was a local condition within the thyroid gland and a small percentage of the operated cases (I say that advisedly) showed definite signs of improvement. But many of the cases that were operated upon, the ones who survived—because early mortality was great—had a recurrence of their symptoms.

I have held for a long time that the condition manifest through the thyroid gland was not a condition that was located entirely within the gland but that we had something more fundamentally involved than that. I have looked upon the autonomic nervous system as a big factor in the condition.

I realize I am not going to present to you a primary cause of hyperthyroidism, but I am going to look more fundamentally than in the thyroid gland for its origin. The pathologists of more recent years have taught us that the individuals developing hyperthyroid states usually show a persistence of embryological structure that is immature, and we conclude in the clinical analysis of many of these patients that they have other constitutional defects, as Dr. Brown has mentioned, or inadequacies that go along with this.

I make these remarks for this purpose: It seems to have taken a long time for the surgeons to come to the conclusion that there is something more involved than a mere thyroid gland structure. I think the presentation of this paper may be a suggestion to us to think more carefully of our patients in regard to operations upon them, because I know of at least two internationally known surgeons who do a great many operations on patients of this kind, and who have in the past few years refused to operate upon such patients unless they can be under careful supervision and control for a period of a year or eighteen months subsequently, such as the psychiatrist would undertake without operation.

I have compiled data upon some 80 cases of hyperthyroidism that have been treated medically, so to speak, as against some 70 that have been treated by operative procedure. The results in the non-operative cases have been equally as favorable as in the operative ones.

When such men as Charles Mayo make the statement (as I heard him make it a few years ago) that in dealing with hyperthyroidism we should only resort to surgery as a last resort, it seems to me that we have to do with a personality representation in which the thyroid gland is simply one of the integral part; and if we are going to deal successfully with our patients, we have to deal with them on the basis of their total personality, looking to sources more fundamental than the mere functioning of a gland, which is only the expanded end of the nervous system, for the cause of the difficulty.

DR. JOHN A. P. MILLET (New York, N. Y.).—I have just one addition to make to what the last discussor has said. It seems to me that his remarks about the autonomic nervous system form perhaps the keystone to this whole problem. The remark that I have to make is with relation to the anxiety factor. It has been brought out by Dr. Brown that latent anxieties have existed in these patients for many years, long before the hyperplasia of the thyroid occurred. It has also been stated by him that these patients for the most part were equally unaware of their autonomic imbalances, as they were of the existence of anxieties. This brings up the whole question of the physiology of anxiety.

We might pause for a moment to think that the latent anxieties of childhood are perhaps fundamentally the expressions of this autonomic imbalance and of the effects that it produces upon the functioning of all the vital organs.

DR. NOLAN D. C. LEWIS (New York, N. Y.).—I should like to emphasize the point that in hyperthyroidism we have one of those conditions in which there are definite constitutional factors as such, where there are releasing factors in the situation, and where we have behavior reactions to study. There are several other such conditions or situations in psychiatry, and it is my belief that the great contributions in the future are to come from studies of this character.

It takes the double-barreled type of mind to carry on such studies, a mind which uses one sight for both barrels, each of which perhaps carries a different bore and a different load of shot, but which hit the mark in the same place.

DR. WARREN T. BROWN (closing) (New Haven, Conn.).—I am extremely thankful to all those persons who discussed the material. There are two or three questions I would like to touch on hurriedly. First, one thing that was mentioned was the capacity of experience which the individual brings into the world as impressionable. I agree thoroughly, it is impressionable, as I pointed out in the paper by saying that each of these individuals has been impressed by a situation which occurred just prior to the onset of the illness.

I also agree that the development of the personality after it is brought into the world is entirely impressionable by a number of things.

The question of heredity was brought up. I agree that none of the families had actual hyperthyroidism, although in pointing out the hereditary pattern, what I wish to say was that in the families of these individuals there was a large amount of irritability, of sensitivity of the nervous system.

One of the discussants remarked that the thyroid gland influences the emotional stability. That point was questioned. The person who questioned it listed a number of things that affect the thyroid gland; among the things he listed were psychic effects. The question answers itself.

As to the selection of cases, these cases were taken at random from the thyroid patients being followed in the department of metabolism and the department of psychiatry at Yale University.

I agree that the term "hyperthyroidism" will probably become obsolete and an important universal term will ultimately be applied.

As to the question of cause of hyperthyroidism, we tried to point out in this material what types of individuals we have found who have developed hyperthyroidism, the actual cause of the hyperplasia of the thyroid gland, I leave to the physiologist.

THE SIGNIFICANCE OF SPECIAL READING DISABILITY IN MENTALLY HANDICAPPED PROBLEM CHILDREN.*

By THORLEIF G. HEGGE, PH. D.,

Scientific Director and School Principal, Wayne County Training School, Northville, Mich., Lecturer, University of Michigan, Wayne University.

Special reading disability is a condition in which the reading status is markedly retarded as compared with achievement in other academic subjects, notably arithmetic, and with general learning ability as measured by intelligence tests. It is implied that normal educational opportunities have been available and that the acquisition of a reading ability in the ordinary sense of the word is not excluded by visual defect. Special reading disability is thus defined by a psychological and educational pattern of abilities and disabilities. No other suitable criteria are available at present. For various reasons these cases have experienced specific difficulties in learning to read as compared with other children of corresponding mental age. This appears to be the only characteristic which all of them have in common.

To Samuel T. Orton goes much of the credit for having brought a functional viewpoint into the foreground as opposed to the earlier concept of congenital word blindness. Most of the work in this field has, however, been done by psychologists and educators, a particularly noteworthy contribution being that of Marion Monroe, who began her work under Orton, later became associated with the Institute for Juvenile Research in Chicago and is now active in Pittsburgh. It is to be regretted that Orton has found so few followers in the psychiatric profession. For the psychiatrist should be in a position to make contributions to several aspects of the

* Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

The author wishes to acknowledge his indebtedness to Robert H. Haskell, M. D., Medical Superintendent of the Wayne County Training School, and to several associates who have carried the main burden of the reading work.

problem and it is probable that the experience thus gained might prove to be a valuable asset to psychiatric theory and practice.

Reading disability is certainly a formidable problem in present day education. It is probable that at least 10 per cent of the public school population is retarded to such an extent as to be in need of correctional work. It is also evident that an extreme reading disability, which is not eliminated in time, is likely to have a profound influence upon the destiny of an intellectually normal individual. The public schools are just beginning to attack the problem of prevention and cure. The outlook is encouraging since we know that almost all cases are trainable and since we have a right to assume that many of them can be prevented. In many quarters ignorance is still profound, however.

Turning to the mentally handicapped we realize that their general limitations render the importance of a special reading defect less obvious in their case. It is our aim in this paper to attempt to show that the problem is a truly significant one in this group also.

Approximately 90 per cent of the high grade moron and the borderline cases will, under present day methods of class instruction, develop a reading ability roughly corresponding to the expectancy for their mental age. When leaving school they will, on the average, have acquired a fourth grade ability and many will read much better than that. In other words, they become literate. Such a reading ability has, in many cases, vocational and recreational value and it always represents an additional insurance against failure in the community as well as against feelings of inferiority. From one-third to two-fifths of the adult American population reads below the sixth grade level. It is therefore evident that the educational standing of properly educated persons who have been diagnosed as mentally handicapped is in harmony with that of other persons of their own social level.

Although the education of the mentally handicapped must stress recreational, manual and vocational activities, social standards as well as educational ideals require that reading be taught to the members of this group who can be classed as trainable. However, if we must teach reading to the mentally handicapped we must also recognize the importance of extreme special reading disability in the group. About 10 per cent of them do not learn to read in school.

All such reading cases must be taught to read, if possible, and in the Wayne County Training School we have long since established the fact that it is possible to teach almost all of those who have a Stanford-Binet I. Q. of 60 or more.

Since 1929 some 80 institutional children have been trained and studied. Special reading disability and mental defect have, to some extent, been differentiated in these cases where formerly the disability had usually been considered a special variant of mental defect. Their final reading status equals that of their peers who never were special reading disability cases. Some test as high as fifth or even sixth grade. Follow-up studies indicate that the reading ability thus acquired is retained and used after cessation of formal academic training and after parole to the community. Progress in reading very frequently is accompanied by a corresponding general classroom progress and by better adjustment. Last, but not least, the change in reading status takes place in approximately two years time, the rate of progress being comparable to that of a normal child in school. On the average, approximately 75 individual half-hour lessons are required. This means that in the course of a year a remedial teacher should be able to reach a classroom full of these children and initiate an improvement which will prevent further waste of effort and aid materially toward a rapid solution of their problems.

In the following we shall limit our discussion to a particularly significant aspect of this development, viz., the relationship between reading disability and maladjustment, and treatment of the disability as a therapeutic adjuvant. Although many workers of today who are concerned with reading disability and problem children are acutely aware of this relationship, we believe that the importance of the problem has not, as yet, been sufficiently recognized with reference to the mentally handicapped. The factors in the remedial treatment situation which presumably aid in personality education and adjustment would also seem to merit a brief discussion.

Admittedly there are cases whose adjustment is not noticeably affected by the special disability or its cure. They may have adjusted; or the reading defect may be, or have become, an insignificant factor in the picture of maladjustment. There are also

exceptional cases who, because of a personality problem, apparently do not respond to a direct remedial approach. We are not concerned with these cases in the present discussion. We have only those in mind in which the special reading disability is found to be a vital factor in the adjustment problems of the child. The majority of the special disability cases seem, however, to belong in this category. This is true even in the selected group of institutionalized mentally handicapped problem children studied by us.

The extreme reading case of the type in question enters adolescence without having made a significant progress in reading. We should note the educational maladjustment which is present in such a case. For six, eight or more years well intentioned ladies have, without success, attempted to teach such a child the basic academic subject. Being a case of special disability, he has a mental level which is significantly higher than his achievement level and he is intelligent enough to be aware of his inadequacy. He is quite likely to feel his disability as a reflection on his intelligence. Most of his friends have left him behind, not only in reading but frequently in other academic subjects as well. Reading is a tool subject, even in the special school. Measured in terms of grades this discrepancy between the reading case and his group may not seem significant. Measured in terms of futility of effort and feelings of failure his retardation is, however, extreme indeed. He has no occasion to seek consolation in the fact that from the standpoint of the high school the accomplishment in his group must also be classed as inadequate. The discrepancy between him and the group is sufficiently important to affect his placement and program; his disability is sufficiently marked to reflect itself in the attitudes of others and it is likely to affect his own attitude. Admittedly the adjustment problems are frequently also related to factors which lie outside the classroom situation, and the disability itself may at times have resulted, at least in part, from maladjustment or from factors which dispose to it. This does not lessen, however, the importance of the reading defect as an ever present stimulus to various types of maladjusted behavior.

Presumably the therapeutic effects of remedial reading do not, to a marked degree, depend upon the type of instructional program offered, provided the program is successful in teaching the pupil

to read. The therapeutic and educational values inherent in individual remedial treatment should, however, be emphasized, and, in the following, we shall have this situation especially in mind. More specifically we shall have in mind our own particular approach. During the crucial initial period this approach requires the pupil to face his problem squarely and he is guided from step to step by means of a carefully integrated selection of phonetic word drills.

The learning situation provides training in and release for basic adjustment processes. Avoidance reactions and compensatory reactions do not bring results and can be controlled. Reality must be faced. The pupil himself must solve his problem. He has a goal and must persist in order to attain it. Under the guidance of the teacher confidence is soon established. Persistence is rewarded from day to day through success and approval. The final result tends to bring the solution of a major conflict of long standing.

The transfer to other social situations may in part be accounted for by this solution of a conflict. Another point is the fact that the learning process implies, to a large extent, the "reconditioning" of attitudes and emotional responses. The organism or personality reacts as a whole to the learning situation. By a process of interaction involving the transfer of emotional reactions through association and substitution, a large number of social situations, persons, places, objects and their representations had become equivalent with one another and with the reading situation in eliciting maladjusted behavior. Speculatively one might say that the "reconditioning" referred to is the reverse process. The "reconditioning" is presumably dependent upon the fact that the disability had become a relatively important agent as compared with other sources of maladjusted behavior. If this condition does not hold, the linkage with other situations is presumably not sufficiently strong. The process of adjustment is greatly enhanced by the changes which gradually occur in the responses from the social environment and by the experience of success on a wider front.

We should finally also remember the teacher-pupil relationship which develops over a period of weeks and months during which time the pupil comes to the teacher almost daily for half an hour's individual training. The situation provides a setting in which the

shut-in and day dreaming child will open up and apply himself. It also satisfies the craving for attention and security common to so many of these cases while, at the same time, the danger of further "conditioning" the child unfavorably with reference to social behavior is reduced to a minimum. Attention seeking mechanisms tend to drop out almost automatically in the reading situation. Attention is focused not so much on the child as on an objective and significant task in which the teacher and pupil unite. The child grows up as learning progresses. When the treatment situation ceases to be functionally meaningful, the last remaining ties are usually severed painlessly.

In recent years we have published several reports on our results, including a number of case studies. Additional detailed reports are in preparation. We have studied the adjustment of our cases, both in the institution and in their subsequent life in the community. It has not been feasible to complete a satisfactory statistical analysis which will account for the importance of the treatment of the reading disability with reference to adjustment. There are, of course, always many factors in operation. But it is at least evident that many of our reading cases, who presented extreme adjustment problems at the time when they were taken for treatment, frequently adjust well and stay adjusted. The following cases are illustrative:

CASE 1.—Thomas, a negro boy, Stanford-Binet I. Q. 60, who at 14 years of age was a non-reader with a general educational age of seven years, five months. Thomas was a case of extreme aggressiveness and incorrigibility. He would go so far as to attack teachers and was a bully with younger boys and a fighter. Constantly attempting to remain in the limelight, and usually by objectionable behavior, he would, when ignored, "lapse into various states of emotion." When thwarted he would go into what was aptly termed "an insane rage," stabbing with a knife on several occasions. He has a good home and before admission his difficulties were, on the whole, confined to the school. A causative connection between learning difficulties and maladjustment is pretty well established in this case.

He was in the institution for half a year before remedial training began. In the course of the following two years and eight months, he reached the fourth grade level. His attitude toward the reading situation was at first markedly emotional; compensatory attitudes, refusals to cooperate, forgetting and breakdown of already acquired responses alternated with manifestations of a desire to learn and a naive and touching pride in minor successes. A turning point came after several months, and progress became rapid. There was a marked transfer to other academic subjects. Behavior gradually im-

proved so significantly that he was paroled at 16½ years of age. He was discharged two years later. For five years he has maintained himself rather successfully in the community under trying circumstances. He has a good job at Ford's. He possesses an excellent mechanical ability, and he builds and repairs radios in his spare time, making some extra money in this way. The radio is his absorbing interest. Tests a year after parole showed no decline in reading and general educational status. There has been a gradual rise in I. Q. from 60 to 67. The I. Q. may be higher at this time.*

CASE 2.—Leon is another negro boy. His father is serving a life term for having murdered Leon's mother, a fact known to the boy. The killing occurred when he was four months old. His only sibling, a brother, is in the state institution for the feebleminded.

Leon spent his early childhood with various members of his mother's family in an atmosphere of vice, crime and poverty. He was troublesome and not wanted. At five years of age he entered his first boarding home and in the following four years he was in ten homes, being unable to adjust in any. Before he was seven years old, he had been in the detention home six times because of vagrancy and objectionable behavior in public places. His failure to adjust in school was apparent from the moment he entered kindergarten, and he was referred for a clinical examination. In the following four years he was given three more examinations by different clinics. At nine he was admitted to the Wayne County Training School after all community resources had signally failed.

For three and one-half years he continued to be extremely troublesome. His problem was similar to that of Thomas, only more difficult. He was more vicious and would also indulge in most serious infantile tantrums, screaming, kicking and destroying property. In contrast with Leon, Thomas had manual ability and some arithmetic ability, and he has no family problem. When admitted, he was mature enough to respond to a constructive program. Leon, on the other hand, has had no accomplishment whatsoever to his credit, had been rejected everywhere, and has had no anchorage in the world. His conflicts go farther back. He was too immature to respond to any educational program. It should be mentioned, however, that he is quite responsive to affection.

The psychiatric social worker tried a program of frequent interviews. Emphasis was placed upon the exploration of old conflicts and the discussion of current difficulties. The attempt was made to establish a feeling of security by giving him exclusive attention and promoting a process of identification with the worker. He was made to accept some of the limitations to domineering behavior which are inherent in a social situation. Correspondence with his father and brother and contacts with an aunt were also arranged.

The worker finally referred him to the research department. He was invited to come in for a few hours each day. He had a room to himself, things

* The outlook continues good although his recent marriage to a low-grade girl, who had become pregnant by him, may affect his destiny unfavorably.

to own and play with, and friendly contacts and guidance. This program was futile because Leon could not really play. The drive for attention and dominance continued to govern his behavior. He did not want things and attention but the satisfaction of being given things upon request and of gaining attention. Refusals resulted in violent tantrums, and the program had to be discontinued.

Attempts to "recondition" him through removal from the group and deprivation of privileges have been equally unsuccessful. Such disciplinary actions had become the response sought, the occasion for a prolonged sequence of tantrums. Moreover, such rejection in his case is bound to elicit the old fear and rage responses and the method also has other limitations in extreme cases of this sort. It was necessary, however, to remove Leon from school in order to protect the peace of the classroom.

Thus we find him at 12½ years of age still the "wild boy" of the Wayne County Training School. His Stanford-Binet I. Q. is 67. Three months ago when he was taken for remedial training in reading his mental age was eight years, four months. This was considered a satisfactory basis for a training program although, being an all-round failure he is, strictly speaking, not a special reading disability case. We are reporting the case at this time because of its extreme nature and because of the highly interesting fact that Leon has responded very well to the remedial reading situation and to our special phonetic training method.

Naturally no predictions can be made. We merely state what is happening. His difficulties in learning are unusually great, but he is cooperative and much easier to handle than was Thomas. There have been no serious manifestations of maladjustment in the treatment situation. He is under control and he is able to focus attention upon the work. The ego drive is finding an outlet in a social channel. That he wants to learn to read is evident, and he is progressing. That behavior has been good in the cottage over a three month period, and that a program in swimming has been beneficial may or may not be significant. The response to the reading situation, however, certainly throws the appeal of this approach into striking relief.

The type of aggressive behavior described is perhaps especially deserving of attention because of its disturbing effects upon group life and because it so clearly suggests a future of delinquency. Several other problems are, however, equally important. For the present, suffice it to say that many of our mentally retarded reading cases had been characterized as unstable or neurotic without a clear realization of the psychological and educational pattern of special disability and its possibilities as a starting point for treatment. We have seen cases in which a definitely threatening psychosis was prevented with the aid of this approach. There are also those who, according to mental tests and other criteria, had been diagnosed as

socially inadequate by reason of mental defect, in other words as feebleminded, and whose status was materially changed.

High-grade defective and mentally handicapped children must be trained for life. Their potentialities must be explored. Their lives must be enriched by every possible means. They respond rapidly to individual help and to accomplishment. Maladjustment in their case is at least as serious from a social viewpoint as in normal children. It takes less to tip the scales in the wrong direction. It is our conclusion with reference to special reading disability in particular that it must be differentiated in these cases from the condition of general mental and educational deficiency and seized upon as a probably useful approach in preventing social inadequacy and in rehabilitating the maladjusted.

DISCUSSION.

DR. LEO KANNER (Baltimore, Md.).—I feel somewhat ill at ease to be asked to comment on a subject at which both preceding speakers have made for themselves a deserved reputation as some of the foremost pioneers and experts. My only excuse for speaking at all is the fact that circumstances have brought it about that my clinic has become a sort of examination, treatment and teaching center for reading disability in the City of Baltimore. I am grateful to Dr. Hegge for having for years emphasized the fact that a relatively low I. Q. should not be made an excuse for neglecting the value of reading disabilities in those children. I may briefly point out three things that strike one in the discussion of reading disability.

The first is the relative newness of our knowledge of it. The first mention of it was made in 1887, the second in 1898, and then there was a long pause until 1917, when Hinchelwood in his book caught the attention of a wider public.

The second is the fact that even though since then many people, prominent among whom were the preceding speakers, have made major contributions to the subject, the reading disability is still unknown to a great number of school teachers, a great number of schools, and a great number of school systems.

The third is the fact that a great many children come to our attention whose reading disability as such is not discovered until they come for psychiatric examination because of behavior difficulties disturbing to the parents, disturbing to the school and, above all, disturbing to the children themselves.

We were surprised by the quick turn which the difficulties take for improvement as soon as the reading disability was discovered and something done about it. The experience of failure, the lack of knowledge as to the cause of failure, has certainly driven a number of children into manifestations which were disturbing, if not alarming. Compensatory boisterousness in school, truancy, enuresis, soiling even, could be helped as soon as the reading disabilities were found and treated.

Dr. Hegge's paper has brought out very beautifully the relationship between personality maladjustment and the existence and later correction of reading disabilities.

DR. JOSEPH ZUBIN (New York, N. Y.).—I should like to say a word about the rôle of prevention in reading disability, especially as applied to personality adjustment. I shall not say anything about such difficult cases as finally reach the psychiatrist, but in New York City about two years ago, the authorities

became concerned about the fact that as many as 100,000 term child repetitions occurred every year and 80 per cent of these were due primarily to reading disability, that is, failure to learn how to read in the first three grades. This represents a sum total expenditure of about $5,000,000 on these children, that is $50 a term. As a result, not only do they fail to learn how to read, but they help to swell the number of truants and eventually land in the courts as juvenile delinquents. The problem there was to see what could be done about it.

At a rather small expense, the WPA in New York, cooperating with the Board of Education, tried out a very simple experiment. It took relatively untrained teachers, teachers who hadn't even taught before, and simply by giving each child a chance to spend about an hour a day with the teacher who was untrained and unskilled in therapeutic methods and even in reading disability method of treatment, these five hours a week produced almost complete recovery from the reading disability in about 80 or 90 per cent of the cases. Apparently the bulk of the children who had been failing to learn how to read had done so not because of some superficial difficulty resulting from the fact that they were either a little hard of hearing or couldn't see so well or because the teacher didn't happen to appeal to them. It is along this road, I think, that the matter of prevention of reading disability lies. That is, do not wait until the child reaches a point where he needs a psychiatrist, but try to get teachers from the very beginning to prevent these cases by proper methods at the start.

DR. G. HEGGE (closing) (Northville, Mich.).—There was one point mentioned by Dr. Monroe that interested me a great deal, because it contained a viewpoint that I had previously heard her express. That was that the prognosis for improvement in behavior seems to be relatively poor in cases of long standing, in which the maladjustment and the disability had been in existence over a long period of time.

The fact is, our cases usually present that picture because of the special selection that occurs in their commitment to our institution. I presume there may be a hidden problem in that, perhaps apparent discrepancy in that Dr. Monroe thought primarily of children of higher intelligence and it is possible that the treatment of reading disability is likely to result more easily perhaps in some of our cases in adjustment than in the normal child whose disability has existed over a very long period of time. I think there is a possibility there.

SYMPOSIUM ON THERAPY INCLUDING HYPOGLYCEMIA.*

MAY 14, 1937.

PRESIDENT CAMPBELL.—We have this morning a symposium dealing with "Therapy Including Hypoglycemia." The first paper on "The Psychiatric Manifestations of Hypoglycemia" will be read by Dr. Edwin J. Kepler and Dr. Frederick P. Moersch of the Mayo Clinic. (Paper read by Dr. Moersch.)

THE PSYCHIATRIC MANIFESTATIONS OF HYPOGLYCEMIA.

BY EDWIN J. KEPLER, M. D.,
Division of Medicine,
AND
FREDERICK P. MOERSCH, M. D.,
Section on Neurology, The Mayo Clinic, Rochester, Minn.

The recent wave of enthusiasm in the treatment of schizophrenia by the so-called insulin shock therapy has as its main theme, the observation and evaluation of the mental reactions of the patient which result from the induced hypoglycemia. In addition, the insulin-shock therapy has afforded us an unusual opportunity to study the mental and nervous phenomena associated with hypoglycemia. It appeared to us that before we could clearly appreciate and evaluate the symptoms and results of insulin-shock therapy in cases of schizophrenia, we should review our records as to the mental symptoms associated with hypoglycemia, no matter what the etiology. It was with this thought in mind that our present study was undertaken.

For many decades it has been known or suspected that diabetes resulted from a deficiency of the intrinsic secretion of the pancreas. However, until about 15 years ago (Harris) little thought was devoted to the possibility that a clinical syndrome, the converse of

* The papers included in this symposium were read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

diabetes, might result from an overproduction of the intrinsic pancreatic secretion. Up to this time only a few authentic instances of low blood sugar had been encountered among human beings and to our knowledge there were no cases on record, in which a train of symptoms could be ascribed to the persistence of an inadequate amount of sugar in the blood. Today, we appreciate the existence of a syndrome as definite for hypoglycemia as for diabetes. It will be strange, indeed, if sooner or later, some bibliographer in his excursions into the archives of the past does not stumble upon a good description of hypoglycemia.

As the majority of symptoms that occur during the hypoglycemic attack are of a nervous or mental nature, it is important that the psychiatrist acquaint himself with the various mental phenomena occurring during the attack. This is especially important as there is no single criterion by which the state of hypoglycemia can be recognized. In a given case the symptoms may present themselves in strikingly different guises. The severity of the hypoglycemic symptoms is so variable that in the mild reactions the mental or nervous symptoms may be entirely overlooked or they may be interpreted as evidence of a psychoneurosis, vagotonia, a toxic condition or as a mild functional indisposition. If the hypoglycemic state is more profound, the mental reaction may be mistaken for an organic cerebral disease, such as alcoholism, organic dementia, encephalitis, paresis, tumor of the brain and so forth.

Etiology and Classification

Since the introduction of the term " hyperinsulinism " there has been an unfortunate tendency to attribute all hypoglycemic states to an excess of insulin in the body. However, in many instances the etiology is by no means so simple. The maintenance of a normal amount of sugar in the blood depends on an exceedingly complex mechanism of which the production of insulin by the pancreas is only one of the elements. Of equal if not greater importance is the liver. This organ is the source of the sugar in the blood and in its absence the sugar of the blood disappears. The rate at which sugar is metabolized by the muscles also affects the level of the blood sugar. Clinically, there is reason to suspect that the amount of sugar in the blood may be influenced by the rate at which sugar is con-

verted into fat. The centers in the brain stem also have an effect on the blood sugar. In addition, the concentration of blood sugar is influenced by the activity of the thyroid gland, the anterior and posterior lobes of the pituitary body, and both portions of the suprarenal glands. In diabetes the influence of all the factors just mentioned has been clearly demonstrated. Hypoglycemia, theoretically, might result from a disturbance in any of these factors and has been known to occur as a result of a disturbance in many of them. In short, the amount of sugar in the blood should be regarded as a trial balance of all the factors which lower or raise it. From what has been said it is apparent that until some of the fundamental problems of normal carbohydrate metabolism are clarified the etiology of hypoglycemia in some cases will remain obscure.

In general, the cases of hypoglycemia fall into two main groups: first, those in which the etiology can be established either before or after death, and, second, those in which the etiology cannot be determined either clinically or by examination at necropsy.* The classification in Table 1 which is based largely on cases we have observed personally, illustrates the complexity of the problem.

TABLE 1.

ETIOLOGIC CLASSIFICATION OF HYPOGLYCEMIC STATES.

I. Induced hypoglycemia.
   This occurs as the result of insulin therapy.

II. True hyperinsulinism.
   Due to tumors (benign and malignant) or hyperplasia of the islands of Langerhans. The hypoglycemia which occurs in the newborn children of diabetic mothers most likely belongs in this group.

III. Hepatogenous hypoglycemia.
   Examples have been encountered in cases of primary or metastatic carcinoma of the liver, fatty metamorphosis of the liver, cirrhosis, acute yellow atrophy, yellow fever, von Gierke's glycogen disease and in cases of poisoning by arsphenamine, carbon tetrachloride, hydrozene, and so forth. Fatal hypoglycemia occurs in animals after removal of the liver.

* The case recently reported by Baker and Lufkin is an excellent example of our inability to determine the etiology of the hypoglycemia in some instances. The patient had spontaneous hypoglycemic attacks for two and a half years. At necropsy no changes were observed which would account for the condition.

IV. Hypoglycemia from suprarenal or pituitary insufficiency.

Clinically, hypoglycemia is occasionally seen in destructive lesions of the suprarenal cortices (Addison's disease) or the anterior lobe of the pituitary body (chromophobe tumors, and so forth). It may occur in experimental animals after hypophysectomy or bilateral adrenalectomy.

V. Hypoglycemia of unknown etiology.

A considerable number of patients who have severe hypoglycemic attacks should be placed in this catagory. The term "hyperinsulinism" is a misnomer when applied to these conditions.

VI. Physiologic hypoglycemia.

This group is comprised of essentially normal individuals who occasionally experience mild hypoglycemic symptoms. Their symptoms are neither progressive nor disabling.

Pathologic Physiology.

Practically all of the symptoms of hypoglycemia can be interpreted as being the result of a disturbance in the nervous system. In decerebrate animals, convulsions continue to occur as the result of hypoglycemia but not after the medulla has been removed. Very little is known of the mechanism by which a subnormal value for the blood sugar produces its irritative or paralytic effects on the nervous system. Observations made on experimental animals, on patients suffering from spontaneous hypoglycemia and on diabetic patients treated both with regular insulin and protamin zinc insulinate indicate that the symptoms of hypoglycemia are dependent more on the rapidity of change in the concentration of the blood sugar than on the actual amount of sugar in the blood. Thus, a patient whose blood sugar has been lowered gradually may have no symptoms whatsoever. In one of our cases of diabetes in which the patient was treated with protamin zinc insulinate there were no symptoms whatsoever although the value for the sugar fluctuated between 28 and 42 mg. per 100 c. c. of blood for several hours. In another case in which the patient had a chromophobe tumor of the pituitary body there was a severe continuous hypoglycemia (30-40 mg. of sugar per 100 c. c. of blood) which was entirely asymptomatic. In this case the hypoglycemia was discovered accidentally in the course of a routine study of the blood chemistry. In some cases of diabetes in which the patients were treated with insulin and in hepatectomized animals, symptoms of hypoglycemia

may appear when the value for the blood sugar is at a normal level. Even granting that the hypoglycemic symptoms are the result of a sudden lowering of the blood sugar we are still in the dark as to how this shift alters the cells in the nervous system. Some observers believe that the symptoms are due to a lack of sugar in the cells (Olmsted and Logan); others are of the opinion that the phenomena are the result of an altered water metabolism (Drabkin and Ravdin). Anoxemia and parenchymatous disease of the nervous system are due to lactic acid and other mechanisms have also been invoked, but none of these theories is particularly satisfying.

There is reason to believe that some of the mild hypoglycemic symptoms are the result of the epinephrine liberated by the organism in its effort to mobilize sugar from the liver. Certainly, it is true that in induced insulin shock the early symptoms are comparable to those following a large dose of epinephrine. The fact remains that we know that certain definite symptoms occur during hypoglycemia, but as to their exact cause, we can only speculate.

With our increasing knowledge of hypoglycemia, evidence is accumulating to suggest that not only do transitory changes in the nervous system occur, but also that irreversible changes of a permanent character may possibly occur as the result of frequent and severe hypoglycemic reactions. This fact must be emphasized as in the treatment of schizophrenia by hypoglycemic shock, repeated severe comas are employed; it is not uncommon for a patient to be submitted to sixty or more comas within a relatively short period. Animal experimentation by many observers, including Stief and Tokay, Grayzel and others, have shown that, following severe hypoglycemia, definite pathologic changes, especially cellular changes both focal and diffuse occur in the central nervous system. These changes consist of areas of sclerotic nerve cells, zones of hyperchromatic changes in the cells and changes in the oligodendroglia and microglia. The changes in the cells appear to be most frequent in the third and fifth layers of the cortex.

Neuropathologic changes among human beings have also been reported by Wohlwill, Baker and Lufkin and others.[17] We have observed definite cellular changes in the cortex of two patients who died of hypoglycemia. The recent report of Baker and Lufkin

on the cerebral changes in cases in which the patients had had hypoglycemic attacks is of interest as the authors found numerous new and old hemorrhages scattered throughout the brain but they attributed the findings in the ganglion cells to postmortem changes. While the clinicopathologic picture is not complete, it is evident that we are dealing with a profound process that may produce changes which are beyond our control and which must be taken into consideration when considering insulin therapy of any type, especially where it is employed to produce frequent and severe comas.

Incidence.

Opinions differ regarding the incidence of spontaneous (pathologic or true) hypoglycemia.* According to some authors one might infer that the disease is almost as common as diabetes. On the other hand, among the first 18,000 patients who were admitted to one of the large Veterans' Administration Hospitals up to 1934 only one instance of hyperinsulinism was encountered and at The Mayo Clinic to date less than 30 patients have been treated for this condition. The difference between these two conflicting schools of thought probably is the result of difference in opinion regarding what constitutes pathologic hypoglycemia and the criteria used in diagnosis. In our opinion severe disabling pathologic hyploglycemia (regardless of its etiology) is a relatively rare condition, but because of its deceptive manifestations it probably occurs somewhat more often than it is recognized.

Hypoglycemic reactions occur with considerable frequency among patients treated with insulin. The reactions are usually mild and are generally recognized and treated by the patient. The reactions following the use of the recently introduced protamine insulin may be very bizarre and may be easily misinterpreted by the patient or physician.

Material for Study.

The material that we have had at our disposal for study was taken from the records of the clinic and from the records from the Rochester State Hospital. We have not included for this review

* The term "hyperinsulinism" is frequently used to include all such conditions.

cases of mild spontaneous hypoglycemia and the mild insulin reactions observed among diabetic patients. All our reported patients have had definite mental and nervous symptoms associated with their hypoglycemic attacks.

We have selected 21 cases of spontaneous hypoglycemia. Of these 21 cases, 9 were proved cases of hyperinsulinism, that is the patients had islet tumors of the pancreas; 12 cases belong to the group of spontaneous hypoglycemia of unknown origin; in 9 of these 12 cases the patients were submitted to abdominal exploration but no tumors of the pancreas were demonstrated. The remaining three patients refused operation. Of these 21 patients 15 were males and 6 were females. The ages of the patients ranged from 18 years to 57 years at the time the correct diagnosis was made. The average age at the time of diagnosis was 43 years. The average duration of symptoms prior to diagnosis was 3½ years. Three patients had had symptoms for 10 years prior to operation. One of these 3 patients had an islet tumor of the pancreas, the other 2 did not. In 7 of the 21 cases the mental symptoms predominated, in 6 the nervous symptoms predominated, but all patients had both mental and nervous manifestations. Six patients in this group had no convulsive attacks. The fasting value for the blood sugar or the value for the blood sugar at the time of the hypoglycemia ranged from 28 to 46 mg. per 100 c. c.

Twenty patients had induced hypoglycemic attacks of rather severe degree. Eight were patients who had diabetes and 12 were patients who were suffering from schizophrenia and insulin had been used as a therapeutic agent. In addition, we have included two cases of hepatogenic hypoglycemia and nine cases of moderately severe hypoglycemia in which the diagnosis could not be definitely established in spite of definite mental or nervous reactions. Four of the patients in the latter cases had convulsive attacks, one was operated on but no tumor of the pancreas was demonstrated.

Mental Symptoms.

In a consideration of the mental symptoms it is well to bear in mind that mental and nervous phenomena are a constant part of the hypoglycemic attack, indeed, at times they dominate the clinical picture. In spite of the many mental symptoms that may occur

during the hypoglycemic attacks there is no single psychic syndrome that in itself is characteristic of the condition. Rarely is the diagnosis of hypoglycemia easy and there is always a peculiar liability to designate the symptoms as neurotic (Jones) or attribute them to some condition other than hypoglycemia.

The psychic manifestations of hypoglycemia are essentially the same regardless of the underlying pathologic change. The severity of the symptoms appears to parallel the severity of the hypoglycemia, although there is a striking individual variation as to the patient's threshold of hypoglycemic sensitivity. Thus, one patient who has 50 mg. of sugar per 100 c. c. of blood will pass into coma while another patient will experience relatively little psychic disturbance when the value for the blood sugar is as low as 30 mg. per 100 c. c. In induced hypoglycemia, the symptoms as a whole are milder than they are in spontaneous hypoglycemia, as they are usually recognized and treated. The main exception is in cases in which schizophrenia is treated with insulin shock; in such cases the reactions may be very profound. On the whole, in a given case there is a tendency for the mental phenomena to follow a certain pattern, but the variations are at times so frequent and so striking that to accept such a statement as a rule might lead to grave errors in diagnosis and treatment.

It is exceedingly difficult to classify the numerous and sometimes bizarre mental phenomena encountered in the hypoglycemic state. The psychic symptoms extend over the entire range of psychiatric symptomatology. In attacks of any severity the attitude and general behavior of the patient are always disturbed. Any one of the following mental states, to mention only the more common ones, may dominate the clinical picture: apathy, irritability, restlessness, fatigue, anxiety, incorrigibility, negativism, automatic behavior, somnambulism, confusion, excitement, disorientation, "drunken behavior," fugue states, unconscious attacks, delirium, mania, stupor, coma. The motor activity may be decreased or increased. Speech is distorted; there may be garrulity, dysarthria or even aphasia. Emotional instability ranges from all forms of anxiousness to querulousness and violence. The character of the thinking becomes confused and sluggish; the patient may be delirious. The trend of thought may remain within reasonable bounds, but obsessions, compulsions and even hallucinations or delusions frequently may be

present. The mental grasp becomes distorted, the patient may become disoriented as to time, place and person. There is loss of memory for events and the patient does not remember the attack. The mental symptoms may be associated with neurologic disorders of varying type, as motor retardation or convulsive attacks of tonic or clonic type. Usually, it is the associated phenomena that occur during the hypoglycemic attack that must aid in making the diagnosis, as the mental picture taken by itself does not spell a positive syndrome. Unfortunately for the diagnostician, the associated phenomena may be wholly lacking and unless one's diagnostic acumen has been sensitized to the possibility of hypoglycemia the condition is likely to be overlooked. So true is this that on our diabetic service the resident physician is instructed to give orange juice to every diabetic patient who is taking insulin and who presents any bizarre or unusual symptoms, regardless of how improbable the possibility of hypoglycemia may seem.

Report of Cases.

The following cases have been selected because of their psychiatric interest. For the purposes of this paper, only the psychiatric features are presented.

Case 1. *Psychoneurosis Versus Hypoglycemia.*—A man, aged 42 years noticed that when he had changed from day to night work four years ago, increasing weakness and periods of mental cloudiness developed. Following a spell of faintness, his physician had found that the value for the blood sugar was 40 mg. per 100 c. c. Exploration of the pancreas in 1933 had not revealed any abnormality. Examination in 1936 had revealed many neurotic symptoms, but no evidence of hypoglycemia. Diagnosis: psychoneurosis. (A single low value for the blood sugar is not sufficient evidence for a diagnosis of hypoglycemia.)

Closely allied to this type of case are those cases in which patients have convulsive attacks as the presenting symptom. Rynearson and Moersch have previously pointed out that convulsive seizures are a very common neurologic accompaniment of a hypoglycemic attack. However, every hypoglycemic attack need not have convulsive manifestations as part of the syndrome and every convulsion need not be assumed to be on the basis of hypoglycemia, as after all, hypoglycemia is a relatively rare condition while convulsive seizures are very common and are due to many diverse causes.

CASE 2. *Epilepsy Versus Hypoglycemia.*—A girl, aged 19 years, had had grand and petit mal attacks for two years. The home physician found the value for the fasting blood sugar to be 83 mg. per 100 c. c. and a glucose tolerance test revealed that the value for the blood sugar was low at the two-hour period. A diagnosis of hyperinsulinism was made and an exploration of the pancreas advised. Examination at the clinic showed that the value for the blood sugar was within the normal range. Diagnosis: grand and petit mal (idiopathic epilepsy).

It is true, as pointed out by Nielsen and Eggleston and others, that in certain cases "epilepsy" is due to hypoglycemia and in every case of epilepsy this possibility should be kept in mind. This relationship is relatively rare and such a diagnosis should be made only after careful study.

The occurrence of psychic changes in cases in which diabetic patients have been treated with insulin is well recognized. Wilder related several interesting cases that belong in this category. In one case, a diabetic woman, "a person of mild manner, usually quite composed, easily pleased and polite came to see me one day indignant and quarrelsome over some minor annoyance. Her dosage of insulin proved to be excessive and she was most repentant the following day when her blood sugar had been permitted to rise to normal." Another of Wilder's patients, a diabetic, was a structural iron worker who, during one of his insulin reactions had descended without injury from the tenth floor of the steel frame of a building, and had no recollection afterward of how he managed to reach the ground. Another instructive case noted by Wilder was one in which a diabetic child was treated with insulin. The child did well in all classes in school except one. It was noted that this subject was taught in the late afternoon, at the time when hypoglycemia was most likely to occur. A light carbohydrate lunch given before this hour immediately improved the child's grades in this subject. At times, however, the mental phenomena present themselves in such an unusual manner that the underlying cause of the condition may be overlooked.

CASE 3. *Induced Hypoglycemia Versus Fugue State.*—A man, aged 21 years, had had severe diabetes for seven years. On two occasions he had had unconscious spells which had been associated with convulsive movements. For some time he had been lax about his diet and his use of insulin. On the evening in question, after he took his usual dose of insulin at 10 p. m., he went to his shack about a half mile from his home, where he was guarding

turkeys. The next thing that he recalled was waking up in the hospital the next morning at 10 o'clock. The father said that about 2 or 3 o'clock on the night in question, the patient arrived in the barnyard and went to the garage where his brother was asleep in a car. The brother was awakened by the opening of the car door which allowed him to slide more or less onto the ground. As the brother approached the patient, the patient started to fire at him with a revolver. The brother immediately changed his course and started for the house. The patient continued firing until he emptied the chambers of his gun. The patient then walked back to his shack. About five minutes after this period of excitement, the brother and father drove to the turkey shack and found the patient on his cot. He seemed dazed and confused and was put to bed. The next morning a physician removed him to the hospital because he was still confused; he remained in this condition until about 10 a. m. The patient insists that he has no recollection of any of these events. Diagnosis: induced hypoglycemia with fugue and amnesia.

Diabetic patients are all too frequently considered psychopathic because of recurring mental upsets when a reduction of insulin will remedy the condition. With our better understanding of insulin therapy in diabetes, severe hypoglycemic symptoms are less frequently encountered as both patient and physician are more alert to the insulin reactions. It must be borne in mind, as noted by Wilder, Jones and others, that a diabetic whose blood sugar has for some time been at a high level may show hypoglycemic symptoms when this level is reduced to what would ordinarily be a normal figure.

Bowen and Beck in 1933 reported a death resulting from insulin hypoglycemia. They said that up to that time Joslin had reported four deaths of diabetic patients who had severe insulin hypoglycemia. That hypoglycemia is not without danger is attested by various reports dealing with definite injuries to the nervous system.

*Case 4. *Severe Diabetes Followed by Spontaneous Hypoglycemia With Evidence of Damage to the Nervous System.*—A married woman, aged 43 years, had had severe diabetes for seven years. The diabetes had been difficult to treat because of alternating periods of resistance to insulin and periods of severe hypoglycemic symptoms induced by small amounts of insulin. Eventually, the administration of insulin had been discontinued; the glycosuria had ceased and spontaneous hypoglycemia had developed. She had had many and diverse reactions. An exploratory laparotomy, which had been performed in 1933, showed that the pancreas apparently was normal. The liver was small and cirrhotic. Microscopic examination of a section of the liver showed extensive fatty metamorphosis and slight portal cirrhosis. During 1935 and

*For detailed report of this case, see Judd, Kepler and Rynearson: Spontaneous hypoglycemia. Am. Jour. Surg. 24: 345-363 (May) 1934.

part of 1936 she had been in a state of hypoglycemia about half of the time. She once had been in hypoglycemic shock from 4 a. m. until well into the afternoon. Even when the value for the blood sugar was as high as 138 mg. per 100 c. c. she had failed to regain consciousness. On various occasions she had had motor palsies, convulsive seizures, a widespread peripheral neuritis, and on one occasion she had had a rather protracted attack of aphasia. In the course of time she had become mentally dull, irritable and seemingly showed evidence of mental deterioration. It was felt that she had sustained some damage to her central nervous system as a result of the hypoglycemic shocks. In recent months there has been some mental improvement, but there seems little doubt that some permanent damage has occurred in her cerebral function. Diagnosis: diabetes, severe hypoglycemic reactions associated with fatty changes in the liver and with apparent injury to the nervous system.

It is in spontaneous hypoglycemia, whether it is the result of hyperinsulinism or unknown causes, that the diagnosis of hypoglycemia may be overlooked, as there is little to direct the physician's attention to the hypoglycemia unless he is familiar with the syndrome of spontaneous hypoglycemia. We have previously called attention to the fact that the symptoms of hypoglycemia may erroneously be attributed to acute alcoholism. Frequently, our patients are advised to carry a slip of paper on which is written: "I am not drunk; I am sick. Make me drink orange juice if you can. If you can't, call a doctor." One of our patients, because of his unusual behavior, was considered to be repeatedly intoxicated, and was discharged from his work. Situations of this character have been noted by many observers. Naturally, such a diagnostic pitfall must be kept in mind when dealing with states of confusion or stupor. As Jordan has aptly said, "It is not seemly for a clergyman to appear intoxicated, and gossip lives on a frugal diet."

As a result of the bizarre and usually transitory character of the hypoglycemic attack, a diagnosis of hysteria is not uncommon, and as is frequently true once a diagnosis of hysteria is made, nothing short of a catastrophe or a miracle will change the diagnosis.

CASE 5. *Hysteria Versus Spontaneous Hypoglycemia.*—A man, aged 42 years, was accompanied to the clinic by his wife, who did most of the complaining. She said that for some months her husband had been having spells of two types. In one type of spell the patient had fallen to the ground, had resisted help, had kicked, had torn things up, had rolled about, but had not injured himself; there had not been a real convulsion. In the other type of spell he had become confused. He said that he felt fine but he did not seem to know where he was or what his business was. He spoke slowly and was unable to reason or to carry on an intelligent conversation. The unusual

character of the attacks led to the diagnosis of hysteria. Closer questioning revealed the fact that prior to the attacks he had had transitory spells of diplopia which strangely enough had disappeared when he had taken food. It was also noted that the attacks usually had appeared early in the morning, before breakfast, or when the patient had been very tired. The value for the fasting blood sugar was found to be 30 mg. per 100 c. c. Abdominal exploration did not reveal any tumor of the pancreas. As a result of a change in the diet, the attacks became less frequent. Diagnosis: spontaneous hypoglycemia with psychic manifestations.

The psychic manifestations during the hypoglycemic state may at times be very profound. Indeed, there may be violence which requires restraint or there may be deep coma. Harris, in 1933, reported a case in which a patient who had depression and delusions of persecution was saved from being committed to an institution by chance response to medical treatment. Wilder reported a case in which some somnambulism and delirium required restraint. He also called attention to the occurrence of psychoneurotic, schizophrenic and convulsive symptoms during hypoglycemia. Greenwood, of the Philadelphia General Hospital, reported several cases in which hypoglycemia was diagnosed as acute confusional states. He mentioned one patient, a man, who had been admitted to the hospital on three occasions with a diagnosis of alcoholic psychosis before the correct condition of spontaneous hypoglycemia was recognized. Similar cases have been reported by Jones, Carr, Wolfe and others.

CASE 6. *Somnambulism, Recurring Attacks of Acute Mania.*—A man, aged 47 years, had had spells of somnambulism for three years; he had wandered out of his apartment and had found himself in some neighboring building. On several occasions he had become irrational and because of a maniacal state had been confined in a straight jacket in a hospital. On one occasion he had been sent to the psychopathic ward of a hospital because of his "unreasonable conduct"; he had been rational during the day, but had had nightly episodes of confusion and delirium. Examination at the clinic revealed that the value for the fasting blood sugar was 35 mg. per 100 c. c. Abdominal exploration did not reveal any tumor of the pancreas. The patient's condition continued about the same as it had been. He died five years later and necropsy revealed an adenoma of the pancreas. Diagnosis: hyperinsulinism with attacks of somnambulism, confusion and acute mania.

Finally, there is a group of cases in which hypoglycemia is likely to be mistaken for organic diseases of the brain, such as tumor, paresis, cerebral vascular lesion, cerebral trauma and so

forth. In practically all these cases, when they are reviewed in the light of the correct diagnosis, the diagnosis appears to be relatively simple. But, as is usually the case, the patients present themselves to the physician under such unusual circumstances that unless the possibility of hypoglycemia is thought of the condition is not recognized.

CASE 7. *Convulsive Attacks, Suspected Tumor of the Brain.*—A man, aged 46 years, was sent to the clinic because of a diagnosis of possible tumor of the brain. Five months previously he had had a generalized convulsion. Since then he had had frequent lapses of memory. A week prior to his admission to the clinic, he had had a more protracted spell of confusion in which he had washed himself in a bucket of drinking water and had completed his ablutions with a pitcher of cream. In spite of the fact that neurologic examination did not disclose any abnormality the possibility of a tumor of the frontal lobe was considered and an encephalographic study was carried out. The results of this examination were negative and the patient returned home. The condition of the patient remained practically the same for about a year and a half, when his physician wrote that he had witnessed a convulsive attack. "The attack he was having was not like any epileptic attack that I have ever seen." The patient was advised to return to the clinic. As a result of a history of frequent spells of confusion that had occurred in the morning and a value of 35 mg. per 100 c. c. for the fasting blood sugar, the diagnosis was relatively easy. Abdominal exploration revealed an adenoma of the pancreas. When the patient was dismissed from the hospital the value for the fasting blood sugar was normal and to date the patient has had no further attacks. Diagnosis: hyperinsulinism with convulsive attacks and spells of confusion.

Other striking examples of psychic disturbances during hypoglycemia could be reported, but these should suffice to call attention to the variable symptomatology of the hypoglycemic attack.

INDUCED INSULIN HYPOGLYCEMIA IN SCHIZOPHRENIA.

Up to the present time (May 8, 1937), we have observed 13 schizophrenic patients under insulin shock therapy. During this time we have observed the mental and nervous reactions during approximately 350 deep comas. It is difficult to compare accurately the psychic phenomena of the mentally normal individual with those of the schizophrenic patient, but it may be said that in a general way practically all the phenomena that are observed in insulin-induced hypoglycemia in diabetes and in spontaneous hypoglycemia are to be observed in the schizophrenic patient. Thus far, we have encountered no evidence of permanent cerebral damage among our

schizophrenic patients. Some permanent cerebral changes have been reported in cases in which the hypoglycemic shock treatment of schizophrenia has been employed and also in cases of spontaneous hypoglycemia. These changes merit a more extensive pathologic report, but attention should be called to the possibility that severe, prolonged and repeated hypoglycemia may result in serious injury to the central nervous system.

As a rule, in the cases of schizophrenia that we have observed, the first symptom of hypoglycemia is increasing drowsiness. This is followed in the majority of cases by a variable degree of motor and psychic excitement, which is comparable to the states of confusion noted in the mentally normal hypoglycemic patients. The period of excitement gives way to coma. Some patients do not experience the stage of excitement, but quietly pass into the state of coma. Some of the more lucid patients said that they seem to be overtaken by a sense of intoxication, or "poisoning" which causes them to pass gradually into oblivion and which leaves them without any memory of the period of coma.

During the coma, many phenomena are observed, such as profuse perspiration, salivation, and motor phenomena of variable degree and pattern. There is a tendency for the symptoms in each case to follow a certain pattern, but psychic variations may occur from time to time. Several patients, while reviving from their coma, would be lucid for several minutes and then resume their usual mental state. This is not unlike the somnambulistic or fugue state seen in other hypoglycemic reactions. We have also observed that following the shock therapy, the mental reaction may change from that of a catatonic stupor to one of catatonic excitement. We have not been able to discover in the motor disturbances of our schizophrenic patients any of the anatomicophysiologic reactions described by Sakel and Angyal and others.

As a result of our experience with these thirteen patients, we have learned that the hypoglycemic reactions in schizophrenia are essentially similar to those observed in patients who are mentally normal, but thus far our studies have contributed only little to a clearer understanding of the effects of hypoglycemia on the nervous system or a better understanding of the mechanism of dementia præcox.

Diagnosis.

The diagnosis of hypoglycemia as the cause of psychic disturbances is not always easy. There are certain cardinal factors associated with hypoglycemia that should at least arouse one's suspicion as to the presence of the condition. These cardinal factors may be summarized as follows: (1) the clinical picture is predominantly one of periodic neurologic or psychiatric episodes; (2) the varying phenomena may present themselves in bizarre form and are usually of a transitory nature, although often of violent character: (3) there is a tendency for the symptoms to occur at certain periods, usually when the patient is hungry or after exertion; (4) the patients appear well between the attacks; (5) the value for the fasting blood sugar or that for the blood sugar during the course of the attack is low; and (6) complete relief from symptoms follows the administration of dextrose.

Before a positive diagnosis of hypoglycemic attacks can be made in a case in which a patient is not taking insulin, it is necessary to show: (1) that the attacks can be precipitated by abstinence from food, (2) that the attacks are associated with a subnormal value for the blood sugar,* and (3) that the ingestion of dextrose will relieve the symptoms. In many instances it is easy to satisfy these requirements. Occasionally, it is very difficult, as the value for the blood sugar after a fast of 12 hours may be normal in some cases in which patients are suffering from bona fide hypoglycemic attacks. If there is good reason, from the clinical history, to suspect hypoglycemia, an effort should be made to induce an attack by exercise and the withholding of food. In one of our proved cases it was necessary for the patient to fast more than 24 hours before an attack could be produced by exercise. It is our opinion that a diagnosis of hypoglycemia should never be made solely on the interpretation of a glucose tolerance curve. Not infrequently, patients suffering from true hypoglycemic episodes have glucose tolerance curves which are frankly diabetic in character, and, conversely, some normal persons have low values for the blood sugar three hours after the giving of dextrose to obtain a tolerance curve. In

* Opinions differ regarding the lower limit of the normal concentration of the blood sugar. In unequivocal cases of hypoglycemia the value for the blood sugar during an attack is practically always less than 55 mg. per 100 c. c.

the latter instances the hypoglycemia (which is rarely of a severe degree) is probably purely physiologic in character. Diagnoses of hypoglycemia are frequently made in cases of gastro-intestinal neurosis, duodenal ulcer, vagotonia, or anxiety neurosis, because of the presence of spells of fatigue which are associated with hunger or mental apathy and are relieved by the ingestion of food. Such a diagnosis in the absence of the criteria just enumerated is not justified. It is this tendency to make a diagnosis of hypoglycemia without adequate foundation that has led to the recent frequent reports in the literature of large numbers of cases of hypoglycemia. Undoubtedly, a great share of these patients are not hypoglycemic, but have functional disorders.

It is of interest to review the various early diagnoses that had been made in the 21 cases with spontaneous hypoglycemia. In most instances, more than one diagnosis had been made in a given case before the correct diagnosis was made. The following are some of the early diagnoses which had been made in these cases: unconscious attacks with or without convulsive features in fifteen cases; acute confusional state in eight cases; stupor or coma in four cases; spells of weakness in four cases; intoxication (alcohol) in three cases; spells of vertigo or dizziness in three cases; tumor of the brain in three cases (an encephalogram had been made in one case); hysteric spells in two cases; acute delirium or mania in two cases; spells of amnesia in two cases; epilepsy (as only diagnosis) in two cases; and lethargy (encephalitis) in one case. It is not surprising that the majority of the early diagnoses were of a descriptive nature. The physicians appreciated that they were dealing with unusual phenomena that did not appear to conform to any of the customary syndromes. Very rarely was the correct diagnosis suspected in the early stages of the disease. Not infrequently, the patient or the family directed attention to the correct diagnosis by their observations as to the time of occurrence of the attack and the knowledge that food relieved the symptoms. By the time the patients were examined at the clinic the diagnoses had grouped themselves as follows: hypoglycemia in ten cases; tumor of the brain in four cases (a ventriculogram had been made in one case and an encephalogram in another); spells of weakness in two cases; spells of stupor or coma in two cases; hysteria in one case; convulsion in one case and a cerebrovascular lesion in one case.

A consideration of the differential diagnosis of hypoglycemia in relationship to the psychic manifestations covers a wide range of conditions. Space will permit mentioning only some of the more common conditions that may be confused with hypoglycemic states. These are functional disorders, especially hysteric attacks; acute alcoholism and drug intoxication; acute confusional states, as fugues, somnambulism, delirium and mania; mild depressive reactions; states of stupor or coma (diabetes and uremia); organic cerebral diseases, as tumor, encephalitis, paresis, cerebrovascular diseases, narcolepsy, and various other organic conditions which produce mental and nervous phenomena as part of their clinical syndrome. It is beyond the province of this paper to consider the differential diagnosis of the various diseases that produce hypoglycemia. If the neurologist or psychiatrist will become "hypoglycemia conscious" he will recognize a hypoglycemic episode when he encounters one or will suspect such a possibility when he evaluates the history of a patient who has had such attacks.

Treatment.

As dramatic and as profound as the mental symptoms of a hypoglycemic attack may be, just so dramatic may be the response to treatment in a given attack. As Carr has said, there is "a surprising and somewhat mysterious tendency toward recovery after the attack has fully developed." There appears to be comparatively little danger of a fatal termination as a result of an isolated severe hypoglycemic attack. The marvel is that a patient in profound shock, in an acute mania or in severe convulsions and who seems on the point of death, may within 10 or 15 minutes get up and eat a hearty meal while engaging in a cheerful conversation, and be entirely oblivious of the apparently precarious state of a few minutes previously. The treatment of the isolated attack consists in the administration of dextrose which is almost uniformly effective. Very rarely one may encounter cases in which the symptoms are not relieved for a long period after the value for the blood sugar has been elevated to normal. The prevention of the attack is more difficult. If the attacks are due to induced insulin hypoglycemia an adjustment in the insulin therapy may obviate further trouble. In spontaneous hypoglycemia, the problem is different.

In most instances it is impossible to determine clinically the organ responsible for the subnormal value for the blood sugar. Consequently, if the symptoms are disabling, a surgical exploration of the pancreas is usually indicated. The results are exceedingly satisfactory if an islet tumor of the pancreas is found and removed successfully. Some of these tumors are malignant and an early operation offers the only chance for cure. Prolonged medical treatment with frequent feedings is inadvisable unless it can be shown definitely that the cause of the disease is not in the pancreas. Such treatment almost invariably brings about great increase in weight and consequently increases the hazards of operation.

Unfortunately, in an appreciable number of cases no tumor of the pancreas will be found at the time of operation. Occasionally, in such cases good therapeutic results have followed partial resection of the pancreas, but in many instances the course of the disease is not influenced by this procedure. Medical treatment then has to be resorted to. As a rule this is not very satisfactory. Drug therapy generally is of little help. Low carbohydrate and high fat diets have been reported to be of value, but as a rule patients who have severe symptoms have to be treated with frequent feedings of carbohydrates.

Summary

It is important for the psychiatrist to appreciate fully the protean nature of hypoglycemic episodes. Invariably, the hypoglycemic attack is characterized by some psychiatric phenomena and indeed the mental symptoms may dominate the clinical picture. As has been pointed out by Allan and others,[18] the psychiatrist is frequently called on to render an opinion in cases in which there are bizarre or unusual mental phenomena and he should be "hypoglycemia conscious." There are three major groups of hypoglycemia, (1) that due to injections of insulin, (2) that due to organic pathologic changes in the pancreas or other organs, and (3) that due to unknown causes. The condition is most prevalent in middle life and probably is not as common as was formerly suspected. In our series of 21 cases of noninduced hypoglycemia, nine were proved to be due to islet tumors of the pancreas and operation offered the only hope of improvement, nine patients were operated on

but no islet tumor was demonstrated; the etiology in most of these cases was indeterminate. The diagnosis of hypoglycemia may be relatively simple if the cardinal factors of the condition are kept in mind. At times, however, the diagnosis may be exceedingly difficult. This is true as all too frequently the patient presents himself for diagnosis under such unusual or trying situations that the neurologist or psychiatrist, unless he is hypoglycemia conscious, will attempt to explain the findings on the basis of some neurologic or psychiatric disorder. The diagnosis of hypoglycemia is usually made early in the disease, although at times eight to ten years may elapse before the nature of the condition is recognized. The symptoms of hypoglycemia may range from mild apathy to mania or coma; there is no single mental syndrome that is pathognomonic of the condition. As important as a low value for the fasting blood sugar may be, a single low value for the blood sugar does not in itself prove that the symptoms are hypoglycemic in origin.

The exact mechanism by which hypoglycemia produces its effects on the nervous system is not known. In our treatment of 13 patients who had schizophrenia we have been able to observe the mental and nervous phenomena during approximately 350 deep comas. Profound changes in cerebral functions occur during hypoglycemia and the possibility that hypoglycemia may produce pathologic changes in the central nervous system should be appreciated. Thus far, we have encountered no ill effects from the use of insulin-shock therapy in schizophrenia.

PRESIDENT CAMPBELL.—When there is a path, to follow it is comparatively easy. To blaze a trail through a practically uncharted region is difficult. In therapeutics many of us utilize methods without thinking very much of the pioneer who outlined these methods. We are at present in a phase of very great interest. We have a path being blazed in a territory which is of the greatest importance. We are very fortunate in having with us today the pioneer to whom we owe a new method of treatment and who has courageously, for a considerable period, carried on this method of treatment. I shall ask Dr. Manfred Sakel of Vienna, Austria, to address us on "The Methodical Use of Hypoglycæmia in the Treatment of Psychoses."

THE METHODICAL USE OF HYPOGLYCEMIA IN THE TREATMENT OF PSYCHOSES.*

By MANFRED SAKEL, M. D., Vienna, Austria.

The American literature has lately contained reports of the therapeutic results and possibilities of the methodical use of hypoglycemia in the treatment of psychoses; it is nevertheless understandable that serious and critical scientists still wait to be convinced, and continue to retain a cautious attitude toward this new therapy. It is not only because an inadequate number of confirmatory reports of the value or soundness of the treatment have so far appeared. I think there are other reasons that could be given and before I proceed to the real subject of this talk, namely the origin and theoretical basis of this therapy, I think it would be well to discuss briefly these other reasons for the prevalence of an attitude of cautious scepticism.

The instinctively cautious attitude adopted by the profession toward this special kind of therapeutic procedure is due to the fact that the basic idea behind it is fundamentally at variance with the biological principles which are ordinarily involved in other therapeutic procedures. The great advances in treatment made by modern medicine in recent years have taught us to expect that every successful treatment has to be based on sound biological principles: a treatment has to fit somehow into the physiological processes with which we are already acquainted. A treatment ought either to eliminate some recognized functional disturbance in the physiological mechanism, or else destroy the actual causative agent of a disease—an infectious agent, for example, can be made innocuous by certain medicines, or a recognized poison, which disturbs the normal physiological processes can be eliminated or neutralized in some way. Modern therapy in recent years has developed consistently along such lines, and even the fever therapy, for example, was neither an unexpected nor an illogical development. When Wag-

* From the Harlem Valley State Hospital, Wingdale, N. Y. Translated from the German by Joseph Wortis, M. D.

ner-Jauregg so brilliantly called the attention of the medical profession to the therapeutic effect of fever, physicians could recall instances in their own clinical experience when one or another psychotic subject was helped or cured by an attack of fever. It was not difficult to come to realize that fever was not a meaningless accompaniment of the organism's struggle against some toxin, but was instead an essential and perhaps indispensable part of the organism's defenses. The discipline of modern science nowadays demands that the first step in the development of a treatment is either to find the toxin that causes the disease, or else to discover what constitutional or functional disturbance is responsible for the symptoms of the disease. It is clear that when a science such as medicine has reached its present high degree of scientific objectivity, there is no room for therapeutic mysticism, or for anything which even suggests it.

Now, how does the hypoglycemic treatment of the psychoses fit into this picture? Does it stand in any kind of analogous relation to the kind of biological or physiological principles we have just mentioned? No, it certainly does not. And this is precisely the difference, which I have just attempted to describe, which all strictly scientifically minded physicians must feel, consciously or unconsciously, in regard to this treatment. But it is nevertheless justifiable to allow an exception in the case of the hypoglycemic treatment, for it has a special and unique position and should not be measured by ordinary standards. This must be so because the fundamental fact is that we do not know the nature of underlying processes of the disease called schizophrenia. In fact, it is still a debatable question whether we are dealing with a disease entity in the ordinary sense at all or simply with a symptomatic clinical picture. And we not only know nothing of the schizophrenic process and schizophrenic diseases, but we know nothing either about the conditions or processes involved in normal thinking, to say nothing of the complicated process that must be involved in an hallucination or delusion.

When we consider our experiences with the hypoglycemic treatment, and more particularly with the hypoglycemic state itself I think we can now say without much fear of contradiction that psychological factors are not likely to be the only ones involved in a mental dislocation as serious as that found in schizophrenia. There

must be some injury to the deeper vital processes as well, perhaps a pathophysiological disturbance, or something perhaps even more complicated. We cannot however dispense with the psychological analysis and understanding of the delusions. There is no substitute for a thorough analysis of the delusions, for that is the only way we can begin to understand the complexes and difficulties of our patient. These problems and preoccupations are merely distorted and transformed by the disease process before appearing in the delusions, but by understanding them, we are enabled to diminish their force and thus relieve the patient.

I have a high regard for strict scientific procedure, and would be glad if we could follow the accustomed path in solving this special problem: it would have been preferable to have been able to trace the cause of the disease first, and then to follow the path by looking for a suitable treatment. But since it has so happened that we by chance hit upon the wrong end of the right path, shall we undertake to leave it before better alternatives present themselves? For even if the hypoglycemic treatment of psychoses accomplishes only a part of what it promises, it nevertheless has a value beyond its therapeutic claims, for it should perhaps now enable us to work backwards from it to the nature and cause of schizophrenia itself.

I am aware that this may prove to be a larger and more difficult undertaking, but I believe it can be said that it is well worth the effort, even though my own theoretical premises, on which the treatment has been based, should finally prove to be wrong. The mistakes in theory should not be counted against the treatment itself, which seems to be accomplishing more than the theory behind it.

The working hypothesis is schematic. The scheme involves a picture of the biological processes and activity of the nerve cell itself, about which we actually know nothing, in contrast to our extensive knowledge of the anatomy, histology and functional localization of modern neurology. The working hypothesis is based on the assumption that the nerve cell is functionally comparable to a fuel engine, so that each of its various functions may be placed in analogy to the functions of such an engine. The nerve cell in other words, like an engine, must have a certain potential energy comparable to that of a running engine that is disengaged. Further-

more the nerve cell, if it is to retain this potential energy, must depend on a continuous supply of endogenous excitant material, comparable to the engine's fuel. Every individual has his own normal nerve cell functional capacity or state of tension, which is sustained by a corresponding amount of excitant hormones. The intensity of potential energy of the nerve cell depends on the proportional mixture of excitant and inhibiting hormones. The level which is normal for each individual is sustained by an automatic regulation. Should the automatic regulation be disturbed by some disease process, then an excess of excitant hormone in the mixture —like too much gas in a motor—can cause an overactivity and therefore a pathological activity of the cell. If the inhibitory factors dominate, then the reaction is weaker, like that of a motor with too little gas. The continuation of the normal tonus of the nerve cell is, in other words, conditioned like the activity of a fuel engine, by both the amount of gas or fuel, and by the kind of regulation. I at first applied this schema to the abstinence symptoms of morphinists. The symptoms that an abstinent morphinist displayed seemed to me to be not primarily but rather secondarily psychological, with the real origin in the vegetative sphere. Since most of the physical symptoms resembled the symptoms of a severe Grave's disease, I concluded that there must be an overstimulation of the sympathetic part of the vegetative nervous system. The sudden onset of the symptoms and their inevitable spontaneous disappearance without treatment in a few days led me to believe that the stimulation of the vegetative nervous system was due to some pathological change in the nerve cell rather than an excess of the excitant hormone, such as we know exists in Grave's disease. I thought that the nerve cell, because of some pathological change, was able to attract more of the circulatory excitant hormone than it usually does. In order to visualize this sudden and transitory affinity of the nerve cell for the excitant hormone, I assumed that the nerve cell was changed by the morphine and that it acquired, to use another figure, additional valences in this way. Let us assume that the normal nerve cell has two valences which have to be saturated with the excitant hormone in order to preserve a normal tonus. If moderate amounts of morphine are administered then one of the valences, having an equal affinity for morphine, becomes

saturated with morphine instead of with the excitant hormone and the result is an abnormal relaxation of the cell. If still more morphine is administered the cell must be stimulated to produce new valences in order to preserve its tone. If, for example, another valence is produced, then there are again two valences which can be saturated with the excitant hormone, so that in spite of the morphine there is no abnormal relaxation of the cell. That is why the morphinist has to keep increasing the dose. This process can repeat itself indefinitely.

The function of the insulin in this abstinence treatment is on the one hand to neutralize the excitant material, and on the other, to cover the unsaturated valences. The success of the treatment with morphinists readily suggested the possibility of using a non-alkaloid to pacify the nerve cell in other excited states. The working hypothesis was up to now proving serviceable.

While using these moderate doses of insulin, it was observed clinically that certain mental or even characterological changes accidentally appeared in certain patients. The assumption of a simply quantitative diminution of cellular function could no longer explain these changes. As such clinical observations were repeated, they could no longer be regarded as accidents but had to be related intimately to the hypoglycemia. Observations like the following could not be overlooked: Patients of an extreme egoism, with an egocentric attitude verging on autism, would become extroverted after an accidental hypoglycemic shock and would become extremely accessible and friendly. This even occurred quite frequently during the first days of abstinence when we were accustomed to see the patients, who were usually quite psychopathic to begin with, become even more asocial than ever.

The fact that stubbornly fixated psychotic character anomalies could be relieved during hypoglycemia and the observation that the rigidity of the personality could be relaxed, sometimes for a sustained period, all led me to think of the possibility of using hypoglycemia as such in the treatment of the psychoses.

I shall later have occasion to talk of the development of the method which made it possible to reach this goal. But for the present I wish to sketch briefly the working hypothesis which guided me in varying the method in different psychotic states.

The assumption that insulin diminished the activity of the nerve cell was sufficient explanation of the sedative effect on excited states but did not serve to explain the mental changes during and after hypoglycemia. The schematic picture which helped me to explain these phenomena was the following:

Activity in the sphere of the nervous system always consists of reactions to stimuli which flow in certain pathways. The changes occurring during hypoglycemia could be explained by the assumption that the hypoglycemia blockades the pathways which happen to be most active at a given time, so that the reactions to the same stimuli now come through pathways which had previously been inactive.

In order to make this picture clear I will take the example of a unicellular organism: Every reaction in this organism too must be regarded as a response to a stimulus, and each cellular function is induced by a signal or stimulus. Each different reaction is dependent on the nature of the stimulus, and both reaction and stimulus are appropriate to each other. In order that this may be possible it is necessary that the whole course of the reaction, from the point of entry of the stimulus to the final end effect, should run through the appropriate intracellular pathway. The more primitive the cell, the fewer the possible varieties of reaction, and the fewer appropriate pathways there must be. At a higher level of development, as new varieties of reaction appear, it becomes necessary for new pathways to develop. When this happens, those pathways which are older in the evolutionary scale are overshadowed by the new pathways that develop and the former fall into the background. In multicellular organisms it becomes necessary to transmit stimuli from one cell to another along fixed pathways in order to allow a given functional activity. At any one stage of development these intracellular pathways are specialized and fixated, and insure a precise performance of the most complicated functions in response to appropriate stimuli, and of course the thinking process is such a function. A stimulus can provoke a reaction only when the stimulus is applied at the appropriate pathway, but not when it is applied to another. If an inapproriate stimulus reaches a certain pathway, it provokes no reaction; a sound wave, for example, produces no reaction on the optic nerve. In the course of long periods of evolution, the course of reactions and the responses to stimuli

become more complicated. The stimuli themselves change in time too—so that it becomes necessary for new pathways to develop. The more ancient pathways sink into the background, but the appropriate relation between stimulus and nerve pathway continues. The most recent pathways to develop are therefore the youngest in the evolutionary scale, and are at the same time the most complicated pathways and those most frequently used.

We know from experience that the youngest and most active organs are most sensitive to injury, and this applies to the nerve pathways. Whenever the nerve cell is injured by some disease process in the organism, either qualtitative or quantitative changes may occur. Qualitative injury to the nerve cell causes injury to the youngest pathways first of all, just as the most recently developed organs in the body are the first to respond to injury. The more severe the injury, the older the pathways are which become involved. The result is that the older pathways must again be activated, and the reactions to stimuli again run across these older pathways. If the injury is very violent there is a distortion and confusion of the intracellular pathways. The former change becomes apparent in the patient's primitive attitude toward the outside world, the latter change manifests itself in the patients disorientation and disorganization. By a process of short circuiting, inappropriate pathways and reactions are involved in the response to given stimuli. A stimulus for example instead of producing a reaction along its appropriate pathway, by means of a short circuit induces reactions over another or several other afferent or efferent pathways. Thus a response may take place over a false pathway by means of a short circuit in spite of the absence of the appropriate stimulus, so that a false sensation is experienced. An olfactory stimulus for example may at the same time, because of a short circuit, induce reactions along both acoustic and visual pathways. This represents the schematic picture of the nature of hallucinations in psychotics, developed from observations on the effect of hypoglycemia on hallucinations.

A clinical example:

A patient who had been having auditory hallucinations for decades, and who had developed a whole delusional system, was subjected to treatment. In four weeks the shock dose was reached. During hypoglycemia, just before the development of coma, the hallucinations disappeared completely for about an

hour. After further treatment the hallucinations not only disappeared for an hour before the onset of coma, but also for another three hours after the termination of hypoglycemia. The patient meanwhile had no physical complaints whatever. This transitory disappearance of the hallucinations was not due to any change in environment or to any physical disturbance, as the following experience shows: For the first few days the patient explained the disappearance of the hallucinations by saying that his enemy was being kept away from him. Later, as he began to observe that the hallucinations disappeared regularly during and immediately after the hypoglycemia, he concluded himself, without any suggestion from others, that "It must be due to some change in me, when those voices disappear during the treatments. It can't be due to something that is being done to my enemy."

I would not call that insight, for the patient's paranoia had lasted too many years for that, but it was interesting to observe the conflict between the paranoid attitude which he could not abandon, and his attempt at a logical solution of the facts.

The following case shows that there are no elements of suggestion or physical change involved in the disappearance of the hallucinations during and after hypoglycemia even in the transitory reactions.

A female patient who presented a picture of paranoid schizophrenia for about a year, associated with purely auditory hallucinations, lost her auditory hallucinations completely after four weeks of hypoglycemic treatment in spite of the fact that she had not yet recovered. She showed no insight, spoke of her hallucinations as of a simple fact, but talked of them in the past tense. She said for example: "I am healthy again, I can go back to my job in Washington. You know that it's been said on the radio that my job is being held for me. You can hear it too." When the examiner paused as if to listen a moment and then said: "No, I don't hear anything. What do you hear?" the patient listened intently for a minute and then said: "Yes, I don't hear anything now either. I haven't heard it for the past few days but it's true anyway."

I shall now only give a short example involving visual hallucinations.

A young girl who had been in the hospital for a few months with a whole system of bizarre delusions which we cannot discuss at present, kept seeing designs, letters and figures on her arm which she imagined that her supposed husband had tattooed there by remote control. She experienced her first shock about 16 days after treatment started and her visual hallucinations thereupon disappeared. When asked again that day, "What about those draw-

ings on your arm?" She thought a while and said: "I think my sight is getting bad, I can't see them now. I've got to give my eyes a rest and then I'll see them again." After her hypoglycemic state was terminated the hallucinations again reappeared but would disappear thereafter during each hypoglycemic treatment for longer and longer periods, and finally disappeared completely. But it still took some time before the patient could look back and appreciate the fact that these delusions were not real.

In all of the examples which I have just given it seems that the hypoglycemia had disconnected the most recent pathways and isolated the short circuits, and thus prevented the false discharge of reactions from appropriate pathways to inappropriate ones. After further manipulation of the hypoglycemic treatment it was possible to blockade and isolate the short circuited pathways so that finally the reactions to stimuli traveled exclusively over appropriate pathways. This picture of the mechanism involved in hallucinations is again merely meant to be schematic.

It is much more difficult to apply this scheme to the abstract and intangible problems involved in the processes of thought or of consciousness. At the risk of getting involved in mythology, the absence of any other helpful picture obliges us to resort again to an hypothesis which will enable us to explain the effect of hypoglycemia on the purely mental processes of thought. We should picture these processes as involving separate cellular units analogous to those of our previous working hypothesis, and these units are again related to different stages of development. To justify, but not to prove, this assumption I shall start with the more concrete and easily observable neurological analogies: I refer to the disappearance of the various reflexes during hypoglycemia and coma in the order of their evolutionary development, as well as the reappearance of these reflexes in reverse order. It cannot be overlooked that the first organic functions to be eliminated are those which are phylogenetically and ontogenetically most recent, with these followed in turn by the older and older ones in regular order. The cremasteric reflex for example disappears first, a Babinski appears at the first sign of coma, while the corneal reflex—which is more ancient—remains active longest, remains in other words most resistant to the hypoglycemia. Similarly, all the other functions are put out of action, layer by layer, as coma deepens and grows more prolonged, with the respiratory center last to be involved. The

temperature center, which I may call a more recent development, is involved earlier. When hypoglycemia is terminated and normal relations are again revived, the first centers to respond are again the older and more resistant ones, for example, respiration, temperature, then the older corneal reflex as the first reflex, the Babinski much later, etc. The special sensitivity of everything that is of more recent development, more complicated and more dominant, is also revealed by the fact that the dominant left hemisphere is more quickly and more completely eliminated.

If we apply all this to mental processes, we may undertake to explain the various reactions to the selfsame hypoglycemic state by saying that here too those components of the mind which happen to be most dominant and active are most quickly and effectively eliminated. In accordance with this assumption we often see that a depression often changes during hypoglycemia to its opposite, so that the patient becomes manic; a manic patient becomes depressed, a confused patient becomes clear or lucid, an excited patient grows calm, or a stuporous patient becomes active again during hypoglycemia. I have therefore been led to assume that the hypoglycemic state first eliminates and inhibits that portion of consciousness in a psychotic subject which happens to be most active at the time, with the result that the other portions—which I may perhaps call the antagonistic part of the patient's mentality—again rise to the surface to again achieve dominance, even if only for a short time. In cases which progress favorably, repeated and correctly managed hypoglycemic states finally serve to produce a permanent dominance of those psychic components which hitherto have been repressed. In this way those portions which had been active before begin to retreat and fall into the background themselves. The remarkable observation of the so-called "activated psychosis" or "reversal of reaction" which I shall later describe, also fits into this picture. All these complicated attempted explanations, however incorrect they may prove to be, were necessary as a working hypothesis in order to develop the extremely complicated hypoglycemic method and technique. This method involves a modification in the time of termination of the hypoglycemic state in various psychotic states, for the most favorable results. This working hypothesis is only a schematic representation of apparently inconsistent clinical observations gath-

ered over a period of years, before they could be used to clarify the modifications of technique.

I will only briefly discuss the nature of this technique, since I feel that even the best description cannot serve to convey more than a vague picture to an audience. Even the most complete description without practical training and experience is not sufficient for a successful trial. Before hypoglycemia could be recommended as a therapeutic principle a technique had to be developed which allowed its systematic use with a minimum of danger. I must however emphasize that the mere technique of the hypoglycemic treatment of the psychoses is only comparable to a knowledge of ligature and asepsis in an operation. That is, it is an absolutely essential condition if dangers are to be avoided. But the success of an operation also depends on sufficient knowledge and experience on the part of the surgeon. In order to handle a hypoglycemic treatment successfully one has to be able to act quickly in accordance with each new situation while the avoidance of dangers ought to take place automatically almost without intruding on consciousness. The technical side of the hypoglycemic treatment in itself tells us nothing about the most important factors in the treatment, namely how each individual case has to be managed. However, the rules for the technique and method have to be strictly followed throughout the treatment, for they are the products of years of experience and careful observation. The fact that we do not yet know the factors which are operative in this treatment does not justify our arbitrarily erecting new principles. Too great an optimism in regard to this method is more dangerous than an overcautious pessimism, since it leads to an amateurish and unsuccessful use of the technique, with the failure finally falsely attributed to the therapy itself. The dangers of the treatment have to be avoided of course, but they ought not preoccupy the physician so much that he forgets the treatment itself, for in many cases favorable results can only be attained when the danger zone is reached.

The Technique

The technique requires that the patient be given increasing doses of insulin until the so-called shock dose is reached, the size of the shock dose varies considerably in different individuals and may be

anything from 15 to 450 units. The initial dose varies from 15 to 50 a day depending on the physical condition of the patient and the duration of his illness, and the doses are increased by 5 to 20 units daily until the shock dose is reached. This constitutes phase 1. By shock dose we understand that amount of insulin which in any individual produces deep coma with areflexia within 4 or 5 hours after one injection. (This is not always necessary.) A shock dose is given 3 to 6 times a week until the desired result is attained but if the patient does not respond no more than 50 injections need be given. This constitutes phase 2. After severe physical manifestations of shock, one or more rest days may intervene, but at least one to three days of rest are allowed every week. These constitute phase 3. Phase 4, which can often be omitted in chronic cases, consists of the administration of a fraction of the shock dose for about eight days, during which marked hypoglycemic reactions are avoided. The insulin injection is always given fasting and is followed in four or five hours by a sufficient amount of carbohydrates. It is often well to give the patient as many grams of sugar as he has had units of insulin. I should like to mention in passing that the blood sugar level, regardless of the amount of insulin given, does not drop beyond a certain level. The neurological symptoms of hypoglycemia or coma are not dependent on any one blood sugar level. I shall not undertake here to give an exact description or definition of the concept of coma or of the somewhat misleading term "shock," as these are things which can be learned in the course of practical experience. I shall only say, to prevent any misunderstanding, that coma should be associated with the absence of the corneal reflex, or at least with the presence of a Babinski. Individual variations have to be made continuously, as therapeutic results cannot be achieved by a stereotyped repetition of hypoglycemic states measured by so many hours, but depends instead on the correct management of each individual hypoglycemic state, and especially on its termination at the right moment. These are matters which can be learned only through long experience.

It would not be proper to neglect psychiatric factors in discussing the treatment of psychoses. Even in an essentially physical treatment of psychoses such as this is, a consideration of psychological and other psychiatric factors is especially necessary. For however

strong the impression may be that we are somehow influencing the psychic processes by means of biochemical processes, it must always be remembered that the opposite is possible as well. The activity of the brain and the very material it deals with in the course of normal physiological processes, are after all purely psychological. It is therefore not a matter of indifference to the mentally sick patient what his psychic problems and conflicts are, for this material must be elaborated under peculiarly difficult conditions, and the preoccupations and problems which he is forced to solve now under such difficult circumstances demand our special attention.

When for example we treat a patient with a peptic ulcer which is not due to a dietary error, it is nevertheless important to consider the patient's diet in the course of treatment, for this can facilitate, disturb or neutralize the cure which we achieve by other means. It is not otherwise in the treatment of psychoses. An incorrect psychological management of the patient's complexes in any psychosis, however organically or pathophysiologically determined, can cause great harm.

What has been said up to now is intended merely to chronologically summarize the development of the hypoglycemic treatment. The same holds true for the hypothetical considerations which served as a working basis for the further development of the treatment. However, mere theoretical considerations which may prove to be incorrect, or a statement of the difficulties of the technique are no proof that the treatment is useful or practicable. I am well aware that serious workers can be convinced only by definite clinical evidence of the value of the treatment. Since I shall not have time here to fully present the clinical evidence of results, I shall only attempt to review a few typical facts which demonstrate both the value and perhaps too the logical soundness of this therapeutic approach.

Even the small doses given at the beginning of treatment often produce marked changes in the psychotic subject. They become calmer and less tense. But these changes do not differ essentially, except perhaps in the quality of the sedative effect from the pacification achieved by other therapeutic measures. But these changes become dramatic and striking when more intense degrees of hypoglycemia are reached. These changes are so specific and dramatic that it is difficult to do justice to them in words. From one minute

to the next, the mental picture changes, so to speak, at a single stroke. One cannot escape the impression that the mental changes move consistently in a single direction. It almost looks as if the patient suddenly acquired, so to speak, a different style of thinking. Completely confused patients suddenly become lucid, even if only for a short time at first. Patients absorbed in their hallucinations suddenly lose them, excited patients grow calm, and in the same hypoglycemic state stuporous patients may be aroused. A paranoid patient for example will suddenly lose his delusions and ideas of reference when the hypoglycemia has reached a certain depth. In fact he gains insight into the abnormal nature of his previous hallucinations. In the early stages of treatment the patients become psychotic again as soon as the hypoglycemic state is ended. This change is so complete and abrupt that it almost seems as if one kind of consciousness had been replaced by another. As the treatment progresses these lucid periods last longer and longer, and the normal personality, so to speak, stays with the patient longer. When one sees over and over again how a patient of this sort achieves lucidity during hypoglycemia, and then becomes psychotic again after he has been given some sugar, how can one doubt that this change is intimately related to the hypoglycemia? The periods of lucidity during hypoglycemia become longer and longer and then begin to extend beyond the period of termination of the hypoglycemia. The periods after hypoglycemia during which the former personality dominates become longer and longer, and qualitatively better, until finally the periods last until the next following hypoglycemic state. One cannot escape the impression that each hypoglycemic period serves to remove another portion of the psychosis, so that the former normal personality can be more and more readily revived. When this has happened, a curious phenomenon develops. A patient that showed his normal personality for a short period during hypoglycemia when treatment began, now at the end of treatment, after he has improved, begins to show psychotic symptoms during hypoglycemia. I have called that the reversal of reaction. One practically witnesses the struggle for dominance between two kinds of consciousness. The consciousness which happens to be most active at a given time is paralyzed during hypoglycemia, so that the repressed consciousness again achieves dominance. The activated symptoms which appear in the course of this

reversal of reaction represent an abbreviated version of the patient's own past psychotic development. Those patients for example who do not respond to hypoglycemia with a complete and sudden even if temporary loss of their schizophrenic shell, may at least respond sufficiently to return for a while to some previous stage in their psychotic development. One can force the psychosis, so to speak, back step by step to its previous stages, and in favorable cases back again to the original prepsychotic personality. It would therefore be incorrect to conclude that the hypoglycemia has a specific anti-psychotic action; it is more correct, as the phenomena of the reversal of reaction and of activated symptoms show, to say that it is that part of the mind which happens to be most active and dominant at a given time which is subdued, to the advantage of the repressed portion. As treatment advances, however, the psychotic residue which is reactivated during hypoglycemia, diminishes and disappears in time. A clinical example:

N. N. A 21-year-old female university student of philology. Her family history seemed to show some taint, but the patient's family was hesitant about giving information. The patient herself was an excellent and unusually talented student up to two years before treatment started. In addition to her studies the patient was also socially active, was brilliant and likable and was always the center of her group. Gradually the patient began to neglect her studies, grew irritable and withdrawn, kept more and more to herself under the pretext that she did not get on with people, but gradually definite ideas of reference developed. It became clear in time that the patient was hallucinating. She finally had to be brought to a hospital where she remained for a year and a half. During this time her condition grew gradually but clearly worse. She was apathetic and unemotional, completely absorbed in the hallucinations and could scarcely be distracted from them for more than a few minutes at a time, to establish contact. She would always sink back into her autism, refused to answer concrete questions to the point, but referred instead to her hallucinations. She said Christ was communicating with her from the cross and was giving her commands, that He accompanied her on an aeroplane but had now multiplied Himself, because there was somebody at each window talking to her in a strange language. The patient herself knew several languages. The patient had no wish to work at all, kept muttering to herself, and conversed with her visions. She took no interest in the outside world, or in her relatives, was untidy and had to be fed. The outlook seemed very poor, and I did not at first expect a response to insulin treatment.

During Phase I the patient showed little response to small doses of insulin, both during and after hypoglycemia. It took a long time—about four weeks—before shock doses were reached at all. The type of shock reaction looked

prognostically poor too. The patient responded to shock doses with extreme excitement, and this appeared to be rather favorable evidence of an emotional response, even though of a pathological nature. Still more time was required until the hallucinations began to disappear for a short time at least during hypoglycemia. In the seventh week of treatment the patient responded to 170 units of insulin by losing her hallucinations about three hours after the injection. At this time she was able to establish contact, but was still emotionally flat and uninterested. She admitted that she no longer saw Christ nor heard his voice, but He had only gone away and would come back again. Half an hour later during hypoglycemia the patient suddenly became very emotional and excited for about half an hour. She then went into coma, which could not however be continued for long, because the patient would always develop sudden respiratory distress. The poor prognosis in the first place, and the unfavorable hypoglycemic reactions made me wonder whether it would be worthwhile to continue treatment at all. But since the mother of the patient insisted, treatment was continued. The patient's hypoglycemic reactions remained the same, but she slowly but surely began to show improvement. For several hours after the termination of hypoglycemia, the patient was sufficiently free of her hallucinations to begin to read papers again, which she had not done for two years. It was also possible to converse with her again. However, she showed hardly any insight into her illness, and was not interested to know why she was brought to a sanatorium in a foreign country. In the course of further treatment the patient developed epileptic seizures on three separate occasions, followed always with retrograde amnesia of short duration. After 12 weeks of treatment the patient began to be symptom-free both during hypoglycemia and thereafter. She no longer had hallucinations or delusions, began to act in a way appropriate to her training and surroundings, played tennis and visited the museums and cinema; she did not do these things spontaneously on her own initiative, but she was interested, and could converse sensibly. Except for a certain loss of spontaneity she was by now almost completely recovered. Since this already exceeded our expectations and since the patient was already under treatment more than three months, the treatment was concluded, to allow the patient to show the further improvement which we often see after treatment is concluded, with the possibility in mind that she could be given a second course of treatment if this did not occur. But after a few weeks she showed so much further improvement that she not only appeared normal to her family and friends but also to the physician after close examination. She no longer had the least trace of abnormality. Two years have since passed and the patient is still perfectly well.

The cases I have discussed were not chosen from the large clinical material because they were particularly favorable. I have had many cases that proved to be failures and in still other cases the treatment did not proceed without setbacks and difficulties. I chose

these cases not because they were successful but because they were good clinical examples of the relation between hypoglycemia and the changes in the mental or psychotic state. I hope that I have been at least somewhat successful in conveying to you the absolutely inescapable impression that one gets in following a case through treatment: that there is undoubtedly an intimate relation between improvement and the hypoglycemic treatment. Psychiatrists need no longer have that paralyzing feeling of insufficiency toward their psychotic patients that they used to have. They can now have instead a feeling that they now possess an instrument with which they can break through the barrier and attack the psychosis, so to speak, at its vital point. This fact alone would mean a great deal even if the statistical results were not as good as they are. When I think again of my own clinical material, which comprises about 300 cases which I have treated myself, to say nothing of at least as many cases which I have seen treated elsewhere, and consider how often I have seen improvement follow the treatment, improvement in many cases amounting to recovery, to an extent which has up to now been unprecedented in schizophrenics, and when I consider the numerous transitory reactions in which schizophrenics suddenly became accessible again, or when I consider the other various changes in the psychotic picture which occur during treatment, the conclusion becomes inescapable that these changes and these improvements were actually caused by the treatment. Regular and repeated changes of this sort cannot be due to mere coincidence. I shall only briefly summarize the results:

In spite of the difficulties there are in preparing statistics in the case of a disease like schizophrenia where there are no objective symptoms with which we can establish the diagnosis or evaluate the results, nevertheless I think that with material as large as mine, it is possible to avoid the errors involved in a smaller group of cases.

I have divided the case material into three groups: recent cases of less than six months' duration, cases of less than one and one-half years' duration and chronic cases of over one and one-half years' duration.

In the successfully treated cases the concept of a full remission is very strictly defined. We have only included those patients in this group who were not only symptom-free, with full insight into their illness, and with full capacity for return to their former work,

but also where one had no intuitive feeling that there might have been some change in personality.

We called those patients good remissions who were completely symptom-free and who had insight and were able to go back to their work, but where one had the intuitive feeling that there was some personality change.

Under social remissions we understand the third group of patients with more or less marked improvement, but who are not however included in the group of successfully treated cases.

In recent cases the treatment has given us over 80 per cent of good remissions with capacity for work of which about 70 per cent are full remissions.

In chronic cases the results are all poorer in direct relation to the duration of the illness. In our group of cases we have had 40 per cent of remissions with capacity for work. The statistics for spontaneous remissions vary with different authors from approximately 5 to 25 per cent. When we consider that the results in our treated cases are several times better than the most optimistic statistics for spontaneous remissions, and when we consider further that the quality of remission in our treated cases is far superior than that of spontaneous remissions, then we are entitled to conclude that the treatment is effective. The impressive reintegration of personality that we saw in the course of treatment of recent cases, led us at first to treat only recent cases and we at first neglected the chronic cases where the chances of recovery seemed so much poorer. But after more intensive experience with chronic schizophrenics in hospitals, my therapeutic experiences led me to change my views.

In the course of the introduction of the treatment to this country I had the opportunity, through the invitation of State Commissioner Dr. F. W. Parsons to conduct a course for the State Hospital System of New York. The case material which was available at the time of the demonstration of the technique to the physicians was not particularly favorable. However, in spite of the unfavorable material it was possible to allow about half of the twenty patients to return to their homes again, in some cases with capacity for work, and a few others with good remissions, while the rest of the patients were at least sufficiently improved to allow them to lead a tolerably human existence in the institution, so that even these re-

sults can now be said to be by no means a matter of indifference, and from a humane medical point of view, definitely positive.

Dr. Ross, Superintendent of Harlem Valley State Hospital, will give you an account of the results of my attempt to sponsor the treatment on a large scale, under the most favorable possible conditions in this country. He will tell you more of the actual cases which were treated either directly by me or under my supervision by the physicians I have instructed.

PRESIDENT CAMPBELL.—At Dr. Sakel's suggestion, we shall ask Dr. John R. Ross, superintendent of the Harlem Valley State Hospital, Wingdale, New York, where Dr. Sakel has been carrying on so much of his work, to follow Dr. Sakel's paper.

REPORT OF THE HYPOGLYCEMIC TREATMENT IN NEW YORK STATE HOSPITALS.

By DR. JOHN R. ROSS, Wingdale, N. Y.

My remarks this morning are more in the nature of a supplement to Dr. Sakel's paper rather than a discussion of hypoglycemia as a whole.

It is not my purpose to theorize or offer scientific explanations concerning the effect of insulin on our patients. What I think interests this group, particularly those physicians who are stationed in State institutions, is what effect hypoglycemia is likely to have on the large group of continued treatment patients that fill the hospitals. Does this therapy offer any hope for long-standing cases? Unless this type of patient can be helped, from our standpoint at least, insulin will have little value because it is quite evident that we do not receive nor are we likely to receive for some time, at least, those patients who are in the very early stages of their disease. If a psychosis which has lasted more than six months or a year will not respond to hypoglycemia, little can be hoped for in the state institutions. With the idea of clarifying this point, Dr. Parsons, the Commissioner of Mental Hygiene in the State of New York, decided the best way to find out was to institute treatment in all of our institutions and check results. Because there is danger to life in this treatment if unskillfully managed, it was felt that it should not be done by untrained individuals. Dr. Sakel was invited to instruct a group of physicians from the different institutions in New York State in his technique, and he very generously contributed six weeks of his time at the Harlem Valley State Hospital giving such instruction. Treatment was begun on December 8, 1936, and Dr. Sakel visited daily.

The patients selected for treatment in this initial group did not offer a good prognosis in a single instance. Before treating, it was necessary to obtain permission from relatives and this was the criterion used in selecting patients. Although the material was poor it gave an opportunity for the physicians to acquire the technique and see dangerous symptoms handled by the discoverer of

the treatment in person. The results obtained from this first group of patients were surprising. With the exception of two all showed a definite improvement and a number were sent home apparently recovered. After this course was finished the physicians returned to their various institutions and started the treatment in their respective hospitals.

I am today reporting the results obtained so far in New York State with this form of therapy: Five hospitals have no statistics available yet, so that the total number of hospitals who have cases where treatment has been finished is 14.

I am reporting the findings at the Harlem Valley State Hospital separately, because treatment has been going on there for a longer period of time than at the rest of the institutions in the state, and it has been supervised by Dr. Sakel from its inception. Of late, weekly visits have kept him in touch with the treatment. The report for the whole state will not include the figures of the Harlem Valley State Hospital, but can be used as a check. This report is "as of April 24, 1937."

At Harlem Valley.

The total number of patients treated and now under treatment is 77. Treatment has been completed in 38 patients. The prognosis in the greater number of these patients was poor; possibly one or two might be called guarded. As to diagnosis, there was a difference of opinion in one or two of the patients treated, but my own opinion is that all were in the dementia præcox group. If there was any question at all as to diagnosis, it can at least be said that the patients were not improving and gave evidence of being individuals who would remain in the hospital indefinitely. Of the 38 completed cases, 19 have been paroled home and of this number, 12 apparently have recovered; 4 were much improved and 3 were improved. Of the patients still remaining in the hospital of these 38, 9 were improved and 10 were unimproved. Percentages are as follows:

	Per Cent.
Apparently recovered	31 +
Much improved	10 +
Improved	31 +
Unimproved	26 +

Among the patients treated was one of a pair of identical twins. One twin was not treated. These individuals came to the hospital about the same time, their psychoses were almost identical as to duration and symptomatology. The treated twin was sent home and on his own initiative obtained a position which pays him $19 a week, and from reports which he makes regularly, he is apparently getting along well. A letter received since making this report states his salary has been raised. The untreated twin was sent home at a later date slightly improved. He was unable to adjust and has been returned to the institution practically in the same condition as when first admitted. He is to receive the insulin treatment and it will be interesting to see the results.

In the entire state the number of patients who have been treated and are now under treatment is 286, exclusive of Harlem Valley State Hospital. At the next meeting of this society, we hope to be able to have statistics that will be of value. The total number of finished cases is 89. Of that number, 39 have been sent home; 23 apparently recovered; 9 much improved; 7 improved. Of the finished patients who still remain in the hospital, 7 are apparently recovered; 10 much improved; 11 improved and 22 unimproved. The prognosis reported from all over the state in the great majority of cases was poor. A few were reported as fair and a still smaller number, actually one or two were reported as good. The latter cases were reported from the Psychiatric Institute in New York City.

The patients paroled home we have called "apparently recovered" because the time under observation away from the institution is altogether too short to make a more definite statement.

From the state the figures in percentages are as follows:

	Per Cent.
Apparently recovered	32 +
Much improved	21 +
Improved	20 +
Unimproved	24 +

If this can be continued, it is quite evident that we have obtained a potent agent to deal with dementia præcox. These figures make us feel that the treatment should be carried on and we hope that other institutions throughout the country that are not now treating will institute such treatment and check against our results.

The State of New York has been fortunate in having the advice and supervision of Dr. Sakel and to him we extend our thanks for instruction and advice. Dr. Parsons, our Commissioner, is pleased to extend the hospitality of our hospitals to other hospitals that wish to send physicians for instruction in the technique. At the next meeting of our organization we should have sufficient information to state definitely as to the value of hypoglycemia.

EXPERIENCE WITH THE HYPOGLYCEMIC TREATMENT OF SCHIZOPHRENIA.*

By SOLOMON KATZENELBOGEN, M.D., HERBERT HARMS, M.D., and DEAN A. CLARK, M.D.,
Baltimore, Md.

Since July, 1936, we have treated 22 patients. We followed Sakel's original procedure as to its essentials, and the special recommendations he laid down in his latest publications. Up to the time of writing this report (end of April, 1937), the treatment had been concluded in 16 patients. Our experience with the treatment in these as well as in the six patients in whom the treatment is not yet terminated, will be discussed under the following headings:

1. Dosage of and tolerance to insulin.
2. Physiological and personality reactions following the injections of insulin.
3. Difficulties and dangers attached to the treatment.
4. Therapeutic effects.

Dosage of and Tolerance to Insulin. Blood Sugar Changes.

The amounts of insulin sufficient to provoke the so-called shock, or hypoglycemic reactions, varied within wide limits in our patients—from 25 to 200 units. In a patient, 60 years old and hospitalized for 14 years, 25 units consistently provoked profuse perspiration, excessive salivation and deep coma. Similar reactions were caused by 35 units in a patient 46 years old and ill for 13 years. After a five-week period of treatment the dose of insulin had to be raised to 45 units in order to provoke coma. On the other hand, in a patient 16 years old and ill for 17 months, there were either mild or no reactions until the gradually increased

We are indebted to the Supreme Council, 33° Scottish Rite Masons of the Northern Jurisdiction, U. S. A., for the financial help granted for our research work in schizophrenia.

amounts of insulin reached 200 units. This dose regularly provoked deep coma. This patient remained dry most of the time during the treatments and only occasionally perspired mildly.

In another patient 17 years old and ill for 18 months, the shock dose which for a certain period of time consistently provoked profuse perspiration and coma was 195 units. Subsequently, gradually decreasing amounts of insulin, down to 100 units, had the same effect. Moreover, during this phase of treatment, the patient reacted with more or less generalized convulsions to 140-100 units. Obviously, the patient's tolerance to insulin was lowered in the course of the treatment.

The dose of insulin to be used also depends upon the kind of reactions which one wants to obtain. In a patient 27 years old and ill for seven months, because of his mutism and inactivity, our aim was to interrupt the treatment at the first sign of activity in speech and action. This was achieved during several treatments with 35 to 80 units. Then, in view of the fact that the patient became extremely restless, combative and confused during the treatments and again mute in between the treatments, we thought it worth trying to provoke coma. In this we succeeded when the gradually increased amounts of insulin reached 150 units.

The lowest blood sugar value obtained four hours after the injection of only 25 units of insulin was 18 mgm. per cent. Values between 20 and 36 mgm. per cent were frequently found. Examination of blood sugar every one-half hour during four hours after the administration of insulin showed that the lowest glycemia was reached from one to two hours after the injection. The low level remained practically unchanged during the subsequent three to four hours. In some of our patients there was a marked disproportion between the dose of insulin and the depth of the hypoglycemia. In all of our patients there was no consistent relationship between the amounts of insulin and the blood sugar values obtained within four hours after the injection.

Physiological and Personality Reactions Following the Injections of Insulin.

The reactions which one commonly observes during the individual treatments are the following: wide fluctuations in the pulse rate; decrease of 20 to 30 and increase of 40 to 60 beats per minute

are not unusual. The lowest pulse rate we observed was 47. Bradycardia usually occurs first after the insulin injection. It is followed by a normal pulse rate or tachycardia if the patient becomes restless. During the coma, the pulse rate is again first decreased and then it goes back to normal or above normal. At times the pulse becomes weak and irregular, but most of the time it is of good quality. The blood pressure changes usually are not beyond physiological variations. The respiration rate fluctuates within narrow limits; the maximum change in one of our patients was from 18 to 28. The deviations below the average normal limits are not significant. Irregular or stertorous respiration or heavy deep breathing during the comatose state are quite frequent. The temperature more often than not decreases significantly and in some patients considerably. In one of our patients the temperature went down from around 99 to 94.8°—94° during several treatments before the patient went into coma. In another patient the temperature dropped during one treatment from 98.3° to 93.2° and in another treatment from 97.4° to 91.6°. A marked elevation of the temperature (axillary temperature from 97° to 102.6°) was noted five hours after the administration of glucose in a patient who was extremely restless and had generalized convulsions during the treatment. The physical examination was negative. The next morning the temperature was 98.4°. The pupils remain most of the time normal or dilated; marked contraction occurs only occasionally. Abolition of corneal reflexes, weakness of the plantar reflexes, or a mild extension of the big toe, muscular relaxation and not infrequently very transitory rigidity were noted in many of our patients during coma. In one patient, 28 years old and ill for seven years, the termination of a treatment by intravenous glucose was followed by the patient's inability to grasp or hold objects with the right hand. One hour later he could use his arm slightly; this condition cleared up within three hours. Tremor around the mouth or of the hands occurs occasionally during the comatose state. Shivering with complaints of feeling cold (chill) is of more frequent occurrence. In one patient, while he was excited, there was tremor of the hands and twitching of the left eye. Intermittent pallor and flushing of the face are of very frequent occurrence. Cyanosis of the face is to be seen at times only in certain patients.

The most common reactions are profuse perspiration and marked salivation, but there are patients who remain consistently dry or perspire very mildly; yet they salivate abundantly and otherwise they react to insulin intensively. More or less marked drowsiness—the patient remaining, however, responsive—is a very frequent reaction irrespective of whether or not he eventually goes into coma.

The most dramatic and also most common reactions are excitement, motor restlessness, confusion, localized and more or less generalized clonic convulsions and deep coma. It was noted in one of our patients that twitchings and convulsions consistently began on the right side of the face, then spread in the right upper and lower extremity; they remained there localized or culminated in generalized convulsions. In other patients, the twitchings were from the start quite marked in both legs, or in the face and upper limbs. The sequence of the symptoms is not always the same either in various patients or in the same patient on different days although receiving the same amount of insulin. Perspiration and slowing of pulse usually become more or less pronounced within the first or second hour after the injections. This is the phase of complete or relative quiet, but it is not infrequently marked by twitchings; the quietness is often followed by restlessness which varies in intensity and duration. Coma is commonly the ultimate reaction. Yet it is during the comatose state that localized or generalized convulsions may take place. Out of our 16 patients in whom the treatment was concluded and the six patients who have been under treatment from three weeks to over two months, only four had convulsions during some of their treatments. Each patient usually reacts along the same pattern throughout the treatments when the dosage of insulin remains within certain limits. Yet the quality, intensity, sequence and duration of the physiological reactions, all other conditions being equal, may vary in the same patient on different days.

The personality reactions, aside from frequent complaints of weakness, do not lend themselves for a general description. Only a few examples will be recorded here for illustration:

A patient, 60 years old, hospitalized for 14 years, mute, uninterested in the environment, uncooperative, talked for a few minutes at the end of certain treatments, when aroused from coma by intravenous glucose. Once he said, "They beat me if I talk," and on another occasion he said that he remained silent because someone would kill him if he talked.

A man, 25 years old, ill around a year and mute about six months, while he was restless said, "Why don't you let me go home, why do you keep me in bed all the time? I am not sick," and then continued rambling from one subject to another. A 16-year-old boy, ill for 17 months, in a state of confusion, bewilderment and motor restlessness, once when aroused from coma said, "Couldn't you cancel the order for tomorrow?" (What order?) "The order to stick me. . . . . Gee, golly! If they stick me again, I won't be here." (Where will you be?) "Well, there won't be any R. B. (his name), that's all." A man 27 years old, ill around seven months, was mute for two months before the beginning of the treatment. After most of the injections he appeared puzzled, confused, frightened, sobbed, "Jesus Christ. . . . ." "God damn damnation, where am I?" He readily took 250 grams of glucose. After that he complained of feeling "Down, down, down." He became very excited, roared, "I am getting God damned sick of these days. I am going nuts—where is my father, where is my mother, where is my sister? God damn, where is everybody"? He gradually quieted down, but continued to ask for his family. He wondered about the treatment and kept on saying, "I don't understand it."

There was no consistent relationship between quality and intensity of physiological and personality reactions, depth of hypoglycemia, and dosage of insulin in different patients, or in the same patient in different individual treatments.

Difficulties and Dangers Attached to the Treatment.

The much dreaded hypoglycemic complication in insulin treatment in general rose to a therapeutic virtue, but it did not rid itself of its hazards. Fortunately, experience shows that in case of menacing symptoms, quick administration of glucose alone or coupled with adrenalin brings the patient rapidly out of danger. One of our patients reacted with coma to five successive treatments with 195 units. During the sixth treatment with 195 units the patient, in his usual coma, suddenly had a collapse of the cardio-vascular and respiratory functions, which rapidly yielded to intravenous glucose and adrenalin. Coma, regarded as the most important therapeutic phase, is allowed to stay from one to two hours, but it commands close observation of the patient. Convulsions, localized and more or less generalized, occurred in four patients during several treatments. Regarding them as dangerous, in contrast to other investigators, we immediately counteracted the effect of insulin with intravenous glucose and adrenalin.

Because of the usually pronounced salivation, aspiration of saliva presents a danger during the comatose state. We were particularly concerned about this possible complication in a patient who on two occasions vomited after the nasal gavage of glucose while he was still drowsy; we therefore substituted the gavage by intravenous administration of glucose during several treatments. Then we returned to the nasal gavage but administered only 300 instead of 600 cc. of a 25 per cent glucose solution. In addition, the glucose gavage was preceded by giving atropine (16 drops of a 1:1000 solution) through the nasal tube. With this procedure, vomiting occurred much less frequently.

Another danger lies in the possibility of aggravation of shock reactions soon after the administration of glucose and of recurrence of shock reactions when they are least expected, namely, a few hours after the termination of the treatment. The recurrence of hypoglycemic reactions took place in three of our patients from four to five hours after the conclusion of the treatments. We learned *post factum* that two of them did not receive the full amount of glucose and ate little. The third patient, in his fourteenth shock treatment with the same dose of insulin, took his usual amount of glucose and ate a substantial lunch. Yet four hours and thirty minutes after the termination of the treatment he developed another hypoglycemic reaction. The blood sugar was 32 mgm. per cent. The reaction rapidly yielded to the administration of glucose.

From our observations we also learned that schizophrenic patients, like normal individuals and diabetics, may have an average normal tolerance to insulin, or a high or a low tolerance. The four patients in whom the minimum "shock" doses were respectively 25 units, from 35 to 80, 195 and 200 units illustrate this point. (See, Dosage and Tolerance to Insulin.) In proceeding cautiously, that is, starting with 10-15 units and increasing the daily dose gradually by 5 units we made the very significant observation that the adding of only 5 units to such high amounts as 190 and 195 units made a great difference in that it provoked the desired but hitherto not obtained comatose state. The tolerance to insulin could not be related to duration of illness.

Finally, some of our patients offered examples illustrating the well known fact derived from studies on experimental diabetes in animals and diabetes in man, *i. e.*, hypo- and hyper-sensitivity to

insulin may remain consistent or may be intermittent throughout the treatments. The intermittent hypersensitivity, acquired in the course of the treatment, accounts for the fact that an amount of insulin which on many occasions had not caused significant reactions, suddenly and for no apparent reason, provoked very serious reactions.

The Therapeutic Effects.

THE MAIN FACTS BEFORE AND AFTER THE TREATMENT.

Out of the 16 patients in whom the treatment was concluded, only the first patient's record will be described somewhat in detail. In the remaining records only the main facts noted before and after the treatment will be outlined.

Case 1.—A girl, 15 years old, from the beginning of school in the fall of 1935, complained of tiring easily. In December, 1935, she gave up school on the grounds of strain. Between December, 1935, and July, 1936, she worked as a housemaid. During six months she held seven positions; she gave up the various positions, usually after 2-3 weeks, because of "overwork."

About ten days before admission to the Phipps Clinic (on July 4, 1936) she became overtalkative, excited, and left her job. At home, she appeared frightened and complained of pains in her head and eyes. She talked of being exhausted, of fear that she would lose her mind. She claimed that people were against her. On one occasion she said the food was doped. She misidentified people and also said she was someone else. She was preoccupied and appeared to be listening to voices and made up new words. Her sleep and appetite were good.

On admission to Phipps, the patient was grimacing, laughed and cried intermittently without provocation and talked inaudibly to herself. When asked about her spirits, she said: "I feel fine, I feel better . . . . I can't speak. I know the Ku Klux Klan by heart. It is so hard, they want to ask me truths—untruthful and everything." She claimed that Masons hated her, that everyone was jealous of her and teased her. When asked whether food at home was all right she said, "I can't tell the difference, sir . . . . they ask me what is p, q, r, ja, the American Zoo. I went through the test of American vaccine. I was taught the Abc's backwards. I never told a lie in my life." She said she saw visions and smelled awful odors. Orientation was good.

The patient is of asthentic habitus. The physical examination is not contributory.

The patient has always talked in her sleep. In high school she had failing grades in English, geometry, biology, and as a housemaid she was inefficient. Her I. Q. 107.

Her personality is described as quiet, sensitive, opinionated, quite a good mixer, not interested in religion or sports.

Mother and father separated when the patient was six years old. The mother was found to be paranoid in 1920 in the Phipps Dispensary.

Preoccupation and lack of attention were very marked most of the time and she had to be spoon-fed. Her behavior suggested that she saw and heard things. Her voices she said were "echoes" which were her own and made her lips move. She believed herself to be a Crown Princess who had lost her birthright by fraud practiced by the church. During her nearly two months stay in Phipps Clinic, she gained weight, but otherwise her condition remained unchanged.

On September 1, 1936, the patient was committed to Spring Grove State Hospital. Upon admission she showed very marked preoccupation, numerous mannerisms, appearing to react to delusions and hallucinations. On October 1, she said she was an Indian princess and expected to become a queen. She also talked in a rambling manner of being related to Captain Blood.

At the time of beginning of the insulin therapy (November 11, 1936), the patient was aimless in her activity, preoccupied, uninterested, apathetic, and would respond to no suggestive stimulus in an effort to re-interest her in work or play. She at times expressed ideas that she was Queen of France; she was careless in dress and about exposing herself; her eating habits were poor; she had to be urged to rise in the morning and throughout the day it was necessary to supervise her routine.

When questioned, she would not answer for long periods of time, would often forget the question asked in her preoccupied state, and would never re-state her experiences in the other hospital or tell her physician's name.

Outstanding Features.—Complaint of tiredness and inefficiency for eight months before the onset of the psychotic reactions. This caused the patient to quit school and to change seven positions as housemaid within six months. Preoccupation. Ideas of persecution. Grimacing, unprovoked laughing and crying. Irrelevant and incoherent talk. Neologisms. Listening to voices, seeing visions, smelling awful odors. Believed herself to be a Crown Princess, an Indian Princess, expecting to become a queen, the Queen of France. Careless in dress. Exposing herself. Poor eating manners. Age 16. Duration of psychosis around five months.

Insulin Treatment.—The treatment was carried out from November 11 to December 19, that is, five weeks. The first dose was 10 units. The amount of insulin was increased by 5-10 units at each of the subsequent injections; the maximum shock dose was 85 units.

From November 11 to November 19, the patient received eight injections, the doses of insulin being between 10 and 50 units. No significant reactions were noted during these eight treatments. From the very beginning and throughout this period of treatment, during which there were no shock reactions, the patient's behavior improved strikingly: appetite was good; she was cooperative, quiet, working about the ward.

From November 19 to December 19, the patient received 13 injections, the doses being from 50 to 85 units. During this period of treatment, she reacted more or less to each injection. The following reactions were noted: Perspiration, complaint of weakness, drowsiness, moaning, difficulty in breathing (noted only once), dilated pupils, marked salivation, coma.

Out of these 13 treatments, in seven the patient was aroused from her comatose state by intravenous glucose in 50 per cent solution. The other six treatments were terminated with glucose given by mouth and followed by the regular lunch meal. During this period of shock treatments, the nurses notes on the patient's behavior after each treatment—the rest of the day—read as follows: Very cheerful, pleasant and cooperative, reading or sewing, helping on the ward.

The fasting blood sugar, before the injections of insulin was around 80 mgm. per cent. On two occasions, about four hours after the injections of 70 and 85 units, the glycemias were respectively 86 and 55 mgm. per cent. On the other hand, four hours after the injection of 45 and 50 units the glycemias were 40 and 39 mgm. per cent.

The progress the patient achieved during the treatment may be briefly stated as follows: already in the period when she did not react at all or reacted mildly to insulin, she brightened up, became cheerful, cooperative, spoke more readily, although still briefly. After three shock treatments, she took much interest in her personal appearance. She began talking spontaneously to the nurses, began reading for long periods and would show knowledge of the general story if quizzed. She began to enjoy visits from her relatives and talked for long periods with her mother, who was delighted with the change. The patient began to look forward to leaving the hospital and to this end she made definite plans. She was somewhat indefinite about what she would do upon leaving; whether to return to school, to remain at home, or to attempt some work. When it was formulated to her that she should make every effort to occupy herself upon leaving the hospital and that it might be a good idea to finish her last year of high school, she fell in with the plan, although in a rather submissive way.

With regard to her previous delusional and hallucinatory experiences, she at first attempted to side-step the issue and then said that she did not have such ideas any longer and that perhaps they were only imaginations. With these statements she smiled and was very happy not to be pressed in this respect.

When questioned about the insulin treatment, she described briefly the increasing fatigue, the onset of hunger symptoms, and the gradual loss of awareness, followed by her unconscious state. In her waking state, she had no conception of the length of time of the coma; there were no dream experiences elicited, and in the patient's own words, she felt as though she had been "merely asleep but nothing more."

The patient was paroled from the hospital in care of her mother December 24, 1936, with the understanding that she will report at bi-monthly intervals for follow-up.

At the time of writing these notes (end of April, 1937), four months after the conclusion of the insulin treatment, the patient has again taken up with her friends, is doing housework in her own home and has made spontaneous efforts to find clerical work. It is felt by the family that she is as well as she was before her illness. Since leaving the hospital she has returned at two-week intervals for interviews. The remission has continued unchanged. The patient herself feels that she has undergone a mental illness for which she has no explanation but that she is well now.

Points of interest:

1. Beneficial therapeutic results were obtained in a patient who showed definite parergasic reactions during five months prior to the treatment.

2. The treatment was of relatively short duration—five weeks.

3. Gradual improvement was noted soon after the beginning of the treatment, although the patient showed little or no reaction to the individual insulin injections.

4. Greater improvement was observed after the treatments which provoked marked so-called shock reactions.

5. There was no consistent relationship between intensity of reactions to insulin and degree of hypoglycemia.

6. There was no consistent relationship between dose of insulin and degree of hypoglycemia.

CASE 2.—H. A. The patient, 25 years old, at the beginning of the treatment had delusions of being doped, auditory hallucinations and peculiar somatic sensations. The duration of his illness was seven months. He received 16 injections, six of which were followed by very severe reactions.[1] He gradually improved in the course of the treatment which was of only one month duration. After the conclusion of the treatment he worked well on the ward and showed no abnormal behavior. The formal mental status examination definitely and very favorably contrasted with the findings before the treatment.

Throughout the treatments, the patient had very pronounced reactions, particularly motor restlessness, and moderately low blood sugar levels—approximately 50 mgm. per cent—following the insulin injections.

The remission lasted nearly three months. Then the patient began to complain of diseases for which he coined names, "brainitis," "blooditis," etc., talked about having "all kinds of phobias" and became uncooperative, profane and vulgar. He remains in the hospital and has shown gradual improvement without further use of insulin.

[1] In this, and in the following abstracts, "severe reactions" are those culminating in the semi-comatose or comatose state.

CASE 3.—Z. R. The patient, 28 years old, before the treatment had ideas of being persecuted by communists, hearing voices giving him conflicting directions and calling him bad names, ... "voices want to keep me here to trap you people," and ideas that his wife was unfaithful. The duration of his illness was six months. He was on insulin treatment from September 9 to November 20, 1936, receiving 31 injections, 24 of which were followed by severe reactions. As the treatment advanced, he gradually became cooperative, industrious on the ward and cheerful. He had more insight into his condition, dropped the ideas about his wife running around with other men, had no delusions and heard no voices. He was discharged on parole January 12, 1937, and shortly afterwards went back to work in the bakery where he formerly worked. Unfortunately, his family arranged for him to live alone in a room and not with them. After about a month of regular work, he became preoccupied, suspicious, developed ideas of being influenced by others, of being doped and felt there was a political plot against him. He returned to the hospital in a much more cooperative mood than at his first entry. A second course of insulin is contemplated, but has not yet been carried out.

The points of interest in this case are: Distinct therapeutic benefit was obtained but it lasted only six weeks. During one treatment he had convulsive movements associated with a blood sugar of 22 mgm. per cent. There was no consistent relationship between severity of reactions, depth of hypoglycemia and dose of insulin.

CASE 4.—J. F. A boy, 16 years old, since April 7, 1936, has been seeing men dressed in black who were going to "get" him. He crawled under his bed to pull them out and called to members of his family for help. In the hospital at the beginning of the treatment the main features were mutism, grimacing, uncooperativeness, resistance, negativism, soiling. Duration of his illness was four months.

The patient received the insulin treatment from July 21 to November 10. He had 48 injections, 23 of which were followed by severe reactions. With the progress of the treatment, he markedly improved in that he no longer soiled, carried on brief conversations, and showed more spontaneous activity. When talked to he was pleasant, cheerful, answered some questions, or smiled and nodded his head. One is justified in speaking of a distinct but moderate therapeutic effect. At the time of writing these notes (end of April, 1937), the patient is much easier to handle on the ward, is doing a full day's work in the hospital kitchen, has been home on short visits. We expect him to leave the hospital on parole shortly.

CASE 5.—E. F. A 25-year-old male was ill around a year. The outstanding features were: Delusions of being persecuted by dope peddlers and of food poisoning; ideas of reference; hearing the voice of God; restlessness, deliroid condition; mutism most of the time for about six months. He received 28 injections, 22 of which were followed by severe reactions. While the patient's responses to insulin were very pronounced, prespiration was either

absent or mild. Some favorable change in behavior was noted after each treatment, but it was frequently limited only to a few hours. The patient also showed slight sustained improvement for three months, being much easier to handle and doing some work on the ward; he has been on visits home. Now. (end of April, 1937), he is undergoing a second course of insulin treatments.

CASE 6.—J. L. The patient, 60 years old, was hospitalized for 14 years. The main facts for the last eight years: Mutism; lack of interest in the environment; uncooperativeness; marked cataleptic reactions. The patient was highly hypersensitive to insulin. Twenty-five units consistently provoked strong reactions, including deep coma and very low glycemias, between 18 and 22 mgm. per cent. He received 32 injections with 25 severe reactions. After several treatments, when aroused from coma by intravenous glucose, he talked for a few minutes (see physiological and personality reactions). There was no permanent therapeutic benefit from the treatment.

CASE 7.—T. G. In this case the following features were outstanding: A long record of disorderly conduct, burglary and imprisonment. Delusions of sexual content. Auditory and visual hallucinations. Passivity feelings. Ideas of reference. Age 32 years. Duration of illness six years.

Before treatment the patient was quiet, seclusive, looking suspicious, and frequently combative for no apparent reason. He was a good worker on the ward, but needed constant coaching. He conversed coherently and relevantly about his past but persisted in his claims that people call him vile names at night and that he hears people or voices making him homosexual advances. He was given 31 injections; 18 were followed by severe reactions. A remarkable change in his behavior was noted already after the first shock treatments. He gradually became more sociable, looked livelier, contented, was spontaneously very active on the ward and obviously enjoyed his work. He ceased his outbursts of temper and no longer expressed delusions or hallucinations. The treatment was concluded on November 20, 1936. In January, 1937, he went home with his family, expecting to go to work immediately. At the time of writing these notes (end of April, 1937) the patient is at home and well. For the last six weeks he has been working in a local cannery twelve hours a day with success.

CASE 8.—F. G. T. Male patient, age 27 years.

Outstanding Features—Ideas that his sexual experiences had something to do with the pregnancy of his sister. Auditory and olfactory hallucinations. Feelings of persecution. Suspicious of food. Self-accusation. Sadness. Preoccupation. Fright. Feeling of being "half a man and half a woman." Unreality feelings. Mutism. Motionless. Crying spells and loud laughter. Passivity feelings. Ideas of reference. Duration of illness around seven months.

The patient was given 57 treatments. He had severe reactions during 39 treatments. In 20 of the latter there was very deep coma, in 11 there were

marked twitchings around the mouth, face, neck, and arms, and in 8 clonic generalized convulsions. Twitchings around the mouth turned into generalized clonic convulsions which on two occasions lasted from one to one and a half hours, but with many 5 to 10 minute intervals free from convulsions. After two treatments which caused convulsions, the temperature at 5 p. m. was respectively 101° and 102.6°. The patient reacted violently to 70-80 units with fright, perplexity, bewilderment, confusion, suicidal talk and fighting to get out of the situation. There was favorable change in the patient's behavior following these violent reactions, but only for one or two hours. There was no favorable change after treatments without severe reactions. With 150 units the reactions were rather mild and culminated in coma. The patient's weight increased from 145 to 157 pounds during the treatment. There was no benefit from the treatment.

CASE 9.—R. E. B. Male, age 18 years.

Outstanding Features—Preoccupation with ideas about his body defects: "My ears are too big and stick out from my head." His "eyes changed color." The Lord kept telling him what to do and say. He heard during the night God's voice telling him to kill himself and he cut himself with a knife on the left wrist. Loss of interest in his usual pleasures. Attitude of hopelessness, resignation and indifference toward his illness. Seclusiveness. Period of agitation; impulsiveness; panicky; confused and bewildered state. Stuporous state, catalepsy, mutism. Posturing with ideas of "flying to heaven." Duration of psychosis about eight months.

The patient had 103 treatments, 50 of which were followed by deep coma. The so-called shock or hypoglycemic reactions (drowsy state before going into coma; occasionally slight twitchings around the mouth; slight perspiration) occurred in this patient only when the gradually increased amounts of insulin reached 200 units. After the termination of each treatment, he more often than not was in good rapport, answered questions correctly, was relevant and coherent in speech and action, although not very spontaneous. This lasted from one to two hours. After some treatments the patient's behavior remained markedly improved during the entire afternoon. His weight increased from 125 to 135 pounds. No durable benefit, however, was derived from the treatment.

CASE 10.—P. M. Male, age 17 years.

Outstanding Features—Seclusiveness. Covering his face with a handkerchief because voices told him to do so in order to prevent germs from coming out and infecting the public. Preoccupation. Open masturbation. Talk of building a trans-Atlantic bridge. Suspicious that people are plotting against him. Mannerisms: Posturing, walking like a soldier with Napoleonic pose and goose-step. Gesturing. No insight: "I am not really sick at all. I have no particular trouble." Duration of illness one year and five months. This patient received the treatment for over three and a half months, with a total of 90 injections, 34 of which were followed by severe reactions with deep coma; on several occasions there were also generalized clonic convul-

sions. The patient first had a high tolerance to insulin: 195 units were needed to cause coma. In the course of the treatment his tolerance was lowered; he reacted with coma to 100 units. There was no change in the patient's behavior during the individual treatments. No benefit was derived from the treatment.

CASE 11.—M. L. G. Female, age 24 years.

Outstanding Features—Unresponsive to environment. Careless of personal appearance. Screaming without apparent emotion. Incoherent and irrelevant talk. Her "mind is divided into four parts." Duration of illness around two years. This patient was hospitalized first for six months, then on parole for a year, and again hospitalized for five months before the beginning of the treatment. She received 67 injections with 55 severe reactions. After several treatments there was some improvement in her behavior, which lasted only a few hours. Now (end of April, 1937), she is considerably more interested in her surroundings, is much easier to care for, takes pains with her personal appearance but is not well enough to leave the hospital.

CASE 12.—M. C. Female, age 36 years.

Outstanding Features—The patient was ill for eleven years with numerous remissions, during which she had been discharged on parole. She has been better usually in summer than in winter. Before the insulin treatment the patient was mute and when spoken to would shield her face with her hands. She was untidy, careless, particularly about exposing herself. She was given 38 injections, 17 of which culminated in severe reactions. Nearly each shock treatment was followed by improvement of the patient's behavior for the rest of the day, or for one or two days free from insulin. No durable therapeutic effects were obtained.

CASE 13.—E. K. Male, 19 years old.

Outstanding Features—Obsessional preoccupation with body weakness and losing manhood because of masturbation. Unwarranted laughter, while expressing depressive mood. Mannerisms: Apathy and periods of very pronounced motor restlessness. Habit deterioration. Duration of illness eight months. The patient was on insulin treatment for two months, during which he had 38 injections. He had severe reactions during 11 treatments. His behavior began to improve at an early phase of the treatment. He began to pay attention to his personal appearance, was in better rapport with the physician and personnel and took an interest in people and things around him. After nearly two months' treatment, he was sufficiently improved to leave the hospital. At the time of writing these notes (end of April, 1937) the patient was at home for two months trying to find work. At the last interview the improvement was found to remain unchanged.

CASE 14.—T. B. Male, 41 years old.

Outstanding Features—Habit deterioration. Posturing. Grimacing. Mannerisms: Laughing and talking to himself. Impulsiveness. Combativeness.

Lack of rapport—mute and not responding at any time. Duration of illness and hospitalization 19 years.

The patient received 17 injections, 12 of which were followed by severe reactions. The duration of the treatment was six weeks. The highest shock dose was between 50 and 60 units. Notwithstanding the intense reactions in each treatment, the therapeutic results were nil. It should be noted, however, that the patient had a relatively small number of treatments.

CASE 15.—O. G. H. Male, 26 years old.

Outstanding Features—Delusions of being doped. Passivity feelings. Incoherent and irrelevant talk. Hallucinations of smell and taste. Idea that the attendant is very close to God and some of the patients are connected with God. Habit deterioration. Duration of illness four years.

The patient has received 48 injections with 30 severe reactions. He responded with the usual reactions. We have noted some improvement with less scattering in his talk, greater cooperativeness in work about the ward and a feeling on the part of the family that he is very much improved.

CASE 16.—V. L. Female, age 32 years.

Outstanding Features—Delusions of persecution—there was a "plot to kill" her; someone was going to "crucify" her; in the hospital she saw two men "with murder in their eyes coming to kill" her. Suspicious of everyone —the doctor might be in a "frame-up" against her. Very poor contact—sitting quietly alone and answering questions by giggling and "no," "not exactly," "all right." At times perplexed, gazing around and moving her lips as if she were responding to someone. Habit deterioration—she refused to eat but swallowed food placed in her mouth, had to be dressed and undressed and sometimes soiled the bed-clothes and her own clothes. Duration of illness around sixteen months.

The patient was treated for one month during which she received 16 injections, with 14 severe reactions. She proved to be sensitive to insulin—the first injection of 20 units provoked very pronounced reactions. The highest shock dose which caused coma was 50 units. There was a favorable change in the behavior of the patient at the very beginning of the treatment, namely, after the second injection, which provoked marked reactions but no coma. The improvement rapidly increased and remained sustained throughout the course of the treatment. She helped with the routine work on the ward and to prepare various things for the operating room, readily joined in conversation, read occasionally, paid considerable attention to her personal appearance, ate well, played the piano and was cheerful with the nurses, patients and physicians.

At the time of writing these notes (end of April, 1937) that is, about three months after the conclusion of the treatment, the patient is at home, very much interested in her family, doing regular housework, taking up her usual social activities. For the last month she has been reemployed by the Federal Government to resume her former position as statistician, which requires rather intricate work and commands a high salary.

Summary and Comment.

I. Therapeutic Effects.

1. Out of our 16 patients treated with insulin a relatively complete remission was obtained in six patients and moderate improvement in four more. One patient (Case 2) remained in the hospital practically working as an attendant (work which he was doing before his illness), and after a three-month remission, relapsed.

This patient, when he got well, was anxious to get out from the hospital and go to work. We kept him for two reasons: first, there was no home for him to go to and no work could be found for him; second, we thought it advisable to keep him for observation. We are inclined to believe, however, that early discharge and favorable living and working conditions might have prevented him from relapsing.

Another patient (Case 3) remained outside of the hospital six weeks and did his usual work for a month, then he relapsed into a condition very similar to that which he presented at his first admission. Here again, we feel that the unfavorable environmental situation—namely, that the patient was not accepted into his own home and family but lived alone in a room—might have contributed to the relapse.

The four other patients in remission (Cases 1, 7, 13, 16) have so far (end of April, 1937) remained outside of the hospital and well, respectively, four months, three and a half months, two months, and about three months. It is interesting to note that in four out of these six patients (Cases 1, 2, 3, 13), the age is between 16 and 28 years, and the duration of their illnesses between five and eight months. In the two patients who relapsed (Cases 2 and 3), the duration of their illnesses was respectively seven and six months. The sixth patient (Case 7) who so far has remained well at home for three and a half months—the age is 32 and the duration of the illness is six years.

2. In six patients (Cases 6, 8, 9, 10, 12, 14), the therapeutic effects are nil. The duration of their illnesses is respectively 14 years, 7 months, 8 months, 17 months, 11 years, 19 years, and the respective ages are 60, 27, 18, 17, 36, and 41 years.

3. The improvement obtained in four patients (Cases 4, 5, 11, 15) has been so far maintained respectively 6 months, 3 months,

2 months and 2 months. The duration of their illnesses is 4 months, 6 months, 2 years, and 4 years and their ages are 16, 25, 24, and 26 years.

A further estimation of the therapeutic effects, as related to the duration of the illness, shows that out of six patients who had remissions, five were ill from 5 to 16 months. Whereas, out of six patients who had not benefited at all from the treatment, in three the duration of their illnesses was from 11 to 19 years and in the remaining three from 7 to 17 months. Thus, early cases appear to be somewhat more promising than old ones. Yet failures are not infrequent even in acute cases. So far, neither success nor failure of the treatment could be related to any grouping of parergasic reactions.

Beneficial therapeutic results evidently are not essentially determined by the length of the whole period of treatment or by the frequency of individual treatments. (Cases 1, 2, 7, 13 and 16.) These five cases show that improved behavior in the very early phase of the treatment, even before the patient shows significant reactions to individual injections of insulin, may forecast success of the ultimately completed treatment. There is no consistent relationship between quality and severity of reactions to individual treatments and therapeutic effects, nor is the relationship consistent between the therapeutic effects, the degree of the hypoglycemia and the amount of insulin used.

II. DOSAGE AND TOLERANCE TO INSULIN.

The shock dose in our patients varied from 25 to 200 units. It was determined by the patient's tolerance to insulin and by the type of reactions we were looking for.

There was no consistent relationship between the shock dose, the duration of the illness and the ages of the patients. In one patient the tolerance to insulin was markedly lowered in the course of the treatment. There was no consistent relationship between dose of insulin and degree of hypoglycemia.

III. DIFFICULTIES AND DANGERS ATTACHED TO THE TREATMENT.

One patient suddenly had a collapse of the cardio-vascular and respiratory functions which rapidly yielded to intravenous glucose and adrenalin.

Convulsions regarded as menacing symptoms occurred in four patients during several of their treatments. Because of hypersalivation, aspiration of saliva during the comatose state presents a danger.

Delayed hypoglycemic reactions occurred in three patients four to five hours after the termination of the treatments. Some of our patients were consistently hyper- or hypo-sensitive or intermittently hyper- or hypo-sensitive to insulin.

IV. PHYSIOLOGICAL AND PERSONALITY REACTIONS FOLLOWING THE INJECTION OF INSULIN.

The physiological reactions in our patients are fairly homogeneous, but there are individual variations. The personality reactions of our patients—in attitude, motility, speech—and particularly the content of their speech during the treatments, before they go into the comatose state and after they are aroused from it, show, all other conditions being equal, a much wider range of individual variations. Many patients showed evidence of moderate discomfort during the treatments. One expressed fear of death once on being aroused from coma. Only three patients, however, made any strenuous objections to repetition of the injections. Each patient throughout the individual treatments usually reacts along the same pattern. Yet the quality, intensity, sequence and duration of reactions, all other conditions being equal, may vary in the same patient in various treatments. There is no consistent relationship between kind and severity of reactions, degree of hypoglycemia, and dose of insulin.

Conclusions.

1. The insulin therapy for schizophrenia has in our 16 cases given results, which may be interpreted as encouraging.

2. Menacing reactions occurred infrequently and were readily averted by the immediate administration of intravenous glucose and adrenalin.

3. Most of our patients raised no serious objection to the treatment, usually had an amnesia for all except the initial manifestations of hypoglycemia (hunger, perspiration, dizziness, weakness).

FURTHER EXPERIENCES AT BELLEVUE HOSPITAL WITH THE HYPOGLYCEMIC INSULIN TREATMENT OF SCHIZOPHRENIA

By JOSEPH WORTIS, M. D., KARL M. BOWMAN, M. D., LEO L. ORENSTEIN, M. D., and IRVING J. ROSENBAUM, M. D.,

New York City.

In the past eight months we have treated a total of 60 patients with insulin hypoglycemia at Bellevue. Of these, 50 were schizophrenic subjects and of these again, treatment has been completed in 30 cases. In three cases treatment could not be completed for special reasons. The method of treatment we employed followed Sakel's own as nearly as possible. We wish to gratefully acknowledge the ready help and advice Dr. Sakel and Dr. Dussik have given us on the occasions of their visits to Bellevue. Our results with the completed cases now stand as shown in Table I. According

TABLE I.

	Duration.			Duration.		
	½ yr.	½-1½ yrs.	Total	Over 1½ yrs.	Unknown.	Total.
Full recovery	7	2	9	2	..	11
Social recovery	3	3	6	2	..	8
Improvement	1	..	1	1	..	2
Negative	4	1	5	3	1	9

to our table we have had full or social recovery in 19 out of 30 cases.

In three incompletely treated cases we had one full recovery, one case improved and one unimproved.

In our second series of 17 cases now completing treatment, results promise to be at least as good as, and probably better than our first series. We regard these results as essentially positive and confirmatory of the reports by Dussik and Sakel, Max Müller, Kronfeld and Steinfeld, Frostig, Berglas and Susec, von Pap and others in Europe. On the basis of our experience we feel that the hypoglycemic insulin treatment is by far the best available treatment for schizophrenia.

This audience knows, however, that statistical tables in psychiatry are not always as eloquent as we would like them to be. If we examine our table again, there are several points which require some explanation. In the first place, the diagnosis of schizophrenia was made by members of our staff in the regular way, and only clear and typical cases were included,* the final judgment in these matters resting with the senior author (K. M. B.). The duration of illness in our cases was measured from the appearance of the first marked mental symptom. As you can see, we have had a relatively large proportion of cases of recent onset, and these again happen to be in young individuals. We have treated relatively few chronic cases of the type that fill our state hospitals, and the few that we have treated have not responded brilliantly. We have had our difficulties of course, in deciding on the date of onset in any one particular case, and these difficulties were especially marked in cases that had been out of touch with family and friends before admission, or where the family had no interest or insight into the patient's earlier behavior. The date of onset therefore often represents the date when the patient first began to become troublesome, and we could no doubt make a general revision of our groups of cases in the direction of increased chronicity without doing violence to the truth. On the other hand a few of our cases may have been incorrectly classified as chronic because they showed one or another peculiarity long before the outbreak of their psychosis, so that the date of onset of the first marked mental symptoms had to be placed further back. We might say that we have often had the impression that the so-called pre-psychotic schizoid personality of certain patients really represented an early insidious onset of the disease process. The tabulation of results, moreover, left room for differences of opinion. We have classified our results as nearly as we could into four main groups:

1. Complete recovery with full capacity for return to former work and no ascertainable defect.

2. Social recovery with capacity for work and without definite psychotic symptoms, but with some ascertainable defect on examination.

* One female case of acute onset recovered completely under treatment, but had some affective features and could not be regarded as a typical schizophrenic.

3. Improved cases, in some cases fit for discharge and with some capacity for simple work, but with definite psychotic symptoms.

4. Unimproved or only slightly improved cases. In some of these negative cases there was marked transitory improvement, or enough subjective symptomatic improvement to have made the treatment worthwhile.

We know that among our improved cases are some that would have improved without any treatment, and in one or two cases we actually saw remissions develop during the period of preliminary observation. However, we thought that if we were to make any comparison between the frequency of remission in treated and untreated cases, we would have to take into account all instances of remission which occurred for whatever reason in our treated cases. In practically all of our cases, however, the relation between treatment and improvement was close and intimate. Our patients grew calmer and more collected after their first injections, grew more lucid and accessible thereafter, and then began to show insight—at first during hypoglycemia and later throughout the day as treatment progressed. Some cases relapsed during treatment but were revived again and in all our cases we have had to fit our treatment to the individual and vary our procedure accordingly.

The average duration of treatment in recent cases was about six weeks, including rest days, with about 25 or 30 marked shock reactions, but some of our most striking remissions occurred within two or three weeks with relatively small shock doses.

We found that our maximum doses of insulin were comparatively high and we not infrequently used single doses above 200 units. In chronic or resistive cases the treatment was more protracted, but we have generally thought it best to conclude or suspend treatment after three months. In a few of our chronic cases we have witnessed an absolute resistance to insulin: these patients showed no marked reaction even to very high doses, and we have learned to regard this resistance as prognostically significant. In general the blander hypoglycemic reactions, with the development of a typical "wet" shock, seemed to be prognostically more favorable.

In a few cases the effect of treatment was simply to change the clinical picture without curing the disease. One of our cases for example emerged rapidly from a catatonic stupor soon after treat-

ment started, but remained paranoid and attempted suicide while on a visit home. In other cases the patient would pass through a transitional stage of paranoia or catatonic excitement soon after emerging from a stupor, while on the way to recovery. In following the course of such cases, one gets the impression that the catatonic state represents the more profound, and paranoia the more superficial physiological disturbance. We have found at any rate that the acute paranoid group, with elements of confusion, were the most promising material for treatment. Florid symptoms, so far as they indicated an acute process, were prognostically more favorable than bland and chronic symptoms which had already embedded themselves deeply in the patient's personality.

RELAPSES.

None of our recovered cases has so far relapsed, and the first of our discharged cases has already been well for six months. We have however, observed that such improvement as we have been able to achieve in chronic cases tends to be unstable, often lasting as long as treatment continues, but followed in some cases by a relapse to the former state soon after treatment ends. These patients have no resilience: the treatment seems to be supportive rather than stimulative to them and the organism cannot sustain the improvement after insulin is withdrawn. Whether continued insulin treatment is indicated in such cases remains an open question. Our own impression is that the insulin tolerance merely increases in these cases after a while, and they remain resistant to treatment.

Relapses during treatment sometimes occur and are of considerable practical and theoretical interest. We do not know whether it is better to increase doses, drop doses, or suspend treatment for a while when this occurs, and we have to be guided by more or less vague clinical considerations or by simple trial and error in any particular case. In one of our female cases, a relapse during treatment occurred coincidently with the menstrual period.

In recent cases we have sometimes observed continued improvement after the treatment was ended, especially after the patient was discharged. Such patients seem to need time before they can attain their equilibrium after they have been shaken by the treatment. And finally in all of our cases, we have observed over and over again

that psychological and emotional influences are important, and good results cannot be expected if these psychological factors are disregarded.

DANGERS.

We should like to say a few words about the dangers of the treatment. Epileptic seizures have been of rather infrequent occurrence in our patients and less than one-third of our patients have had them. Though we have had no fatalities in our series of cases, we do not underestimate the dangers of treatment.* We have so far, witnessed no cases of pulmonary edema, and none of our cases has ever developed a status epilepticus. We have seen two instances of hemiplegia following coma, both transitory, as well as three instances of transitory aphasia associated with right facial weakness. Of the thousands of hypoglycemic states which we have witnessed, we have seen but two instances of alarming vasomotor collapse; both of these patients were revived, though one of these remained in danger for several hours. This patient was a boy of 15, of asthenic build, who suddenly developed symptoms of collapse at 11 o'clock one morning, four hours after an insulin injection of 105 units:

> This started with a Jacksonian seizure involving his left side, followed immediately by the development of a thready pulse and a marked cyanosis which changed within about a minute to a grayish pallor. The patient was quickly given a sufficient amount of intravenous glucose to permit him to awaken and to swallow 300 c. c. of sugar solution (containing over 100 grains of sugar), after which he was able to mumble that he felt "O. K.," but within a few minutes he relapsed into coma and his pulse again grew weak. He was thereupon given a subcutaneous injection of seven and one-half grains of caffeine sodium benzoate and another 50 c. c. of 50 per cent glucose intravenously. His pulse improved but he remained in a coma. An hour had by now elapsed since the patient had been given the sugar by mouth, but he was still in coma and we felt that his condition was serious.
>
> At 1.15 p. m.—over two hours after the first collapse, and more than six hours after his insulin injection, the patient was given an injection of 50 c. c. of intravenous glucose to which he did not respond. The patient had by now

* One of our patients (J. J.) died at another hospital three months after his transfer and four months after his last insulin shock. The death occurred one evening three and a half hours after a tube feeding, and was sudden, unexpected and unobserved; no post-mortem examination could be made, and the cause of death remains unknown.

been given 120 c. c. of 50 per cent glucose solution by vein. Although there was no evidence of increased intracranial pressure, a spinal tap was performed and 15 c. c. of spinal fluid was drawn. Immediately afterwards the patient suddenly vomited in a projectile fashion a large quantity of clear gastric contents unmixed with bile. By this time we were beginning to feel rather helpless. We did not understand the patient's condition, and did not know what to do for him. And since we could do nothing, we knew of no reason why the patient should spontaneously revive. Under the circumstances we began to theorize: The quantity and color of the vomited fluid showed that the sugar solution had apparently not passed the pylorus, but had been practically fully retained in the stomach, and this suggested the presence of a pyloric spasm. On the assumption that a pyloric spasm indicated excessive vagus tone, we decided to administer both atropin and adrenalin. The quality of the patient's pulse was fairly good at this time; the rate fluctuated between 90 and 100, but at intervals the patient would grow extremely pale.

The patient was therefore again given 150 c. c. of a 40 per cent sugar solution by tube and at 2.15 p. m. was given 5 minims of adrenalin hypodermically. His color improved at once and in a few minutes he began to make occasional slight facial movements. He was thereupon given an additional .5 c. c. of adrenalin hypodermically, and at the same time 1/150 gr. of atropin. The patient's face grew flushed, his general appearance improved and he began to make slight resistive movements when tickled or pinched. He was thereupon given still another c. c. of adrenalin hypodermically and soon afterwards another 7½ gr. of caffeine sodium benzoate. Soon after this injection the patient again vomited a little. By 4 o'clock the patient was beginning to mutter. An additional 100 c. c. of 50 per cent glucose was administered intravenously at 4.35 p. m. The patient at this time was beginning to show a degree of restlessness which made it necessary to hold his arm, and he presented a general picture closely resembling a catatonic stupor. The patient's response to this final administration of intravenous glucose was excellent and in a few minutes he was fully aroused, though still markedly confused. His blood pressure at this time was 148/88. He looked vacantly about, made vague uncoordinated gestures, mistook a drinking cup for a urinal and was resistive and apprehensive when approached, though still very weak. He was however, by now out of danger and was fully recovered in a day or two.

Our impression is that this patient was saved by the adrenalin and continuously repeated intravenous glucose administrations, but an experience of this sort impresses us with our ignorance of what goes on in the organism during hypoglycemia. If the mystery of schizophrenia is now no longer impenetrable, it remains a mystery just the same, and we now have another mystery to place beside it—that is, the nature and mechanism of the schizophrenic's reaction to hypoglycemia. We are still far from understanding it, but we hope that this new problem will not be so hard to solve.

EXPERIENCES WITH THE HYPOGLYCEMIC SHOCK TREATMENT OF SCHIZOPHRENIA.

By G. ALEXANDER YOUNG, M. D., RICHARD H. YOUNG, M. D., and L. ROUCEK, M. D.,

Omaha, Nebr.

Introduction

Our experience with the hypoglycemic shock treatment of schizophrenia, as described by Sakel,[1-3] Müller[4] and others, is, at this time, based upon 41 cases which have completed or are under treatment. This experience has brought before us certain facts which can be discussed under the headings of Physiological, Biochemical and Psychobiological observations, the description of which is the main object of this paper.

The interest stimulated by previous reports by Sakel and Müller of a high percentage of remissions makes necessary for comparison an evaluation of our clinical results. This is done reluctantly and with doubts as to the reliability of such data. Of the 41 cases, 31 have completed treatment. Eighteen (58 per cent) of these cases appear to have obtained a remission, in the sense of a freedom from psychotic manifestations and an ability to make a social adjustment. Four (13 per cent) cases are classed as showing a clinical improvement, and one of these, since returning home, has progressed to an apparent remission. Seven (22.5 per cent) cases are unimproved. Two (6.5 per cent) cases died.

Our experience so far suggests a more favorable response in men than in women. Of the 31 completed cases, 17 were men and 14 were women. Of the 17 men, 13, or 76.5 per cent, showed remissions, while of the 14 women, only 5 or 35.7 per cent were classed as remissions.

We feel that the report of results is presented without an adequate control series. The private cases under treatment were also given psychotherapeutic attention and made use of the opportunities for occupational and recreational therapy that a psychiatric division in a general hospital provides.

It is of interest to report that our cases at the Douglas County Hospital, where there is very little opportunity for psychotherapy,

occupational or recreational therapy, showed what has been termed a remission in 64 per cent in the completed cases. In private practice, the per cent was 54. As another attempt at control, the last 25 consecutive cases in private practice diagnosed as schizophrenic reactions and treated by two of us (G. A. Y. and R. H. Y.) before insulin therapy was started, showed a marked amelioration in psychotic symptoms in 32 per cent.

In reviewing our cases treated before insulin, it appeared to us that the amelioration was, in the majority of cases, less marked and improvement progressed at a much slower rate.

Material

Since early October, 1936, cases under our care have been selected from the private psychiatric wards of the Nebraska Methodist, Lutheran and St. Joseph Hospitals (18 cases) and from the psychopathic wards of the Douglas County Hospital (23 cases) for this treatment. Eli Lilly and Company generously supplied the insulin for the treatment of the County Hospital cases which was carried out under the immediate supervision of one of us (L. R.).

The age range of the group was from 16 to 47, the majority being in the third decade.

The duration of the illness was arbitrarily dated back to the time psychotic symptoms were first noticed by friends or relatives. Seventeen (55 per cent) of the cases were classed as of less than six months' duration; 10 (32 per cent), of 6 to 18 months' duration; and four (13 per cent), more than 18 months.

With regard to nosology, it should be stated that the attempt was made to interpret the total picture in these cases rather than to apply a diagnostic label. An evaluation of the behavior reactions presented revealed that the term schizophrenic or parergastic (A. Meyer) reaction type might be applied to the more prominent features of the illness.

Physiological Observations.

Certain of the physiological features of hypoglycemia are too well-known to include in this paper, and our discussion will be limited to the more variable features and to experiences that have received little mention.

SHOCK DOSAGE.

The dosage necessary to produce coma was quite variable, and unpredictable from an insulin tolerance test taken before treatment was instituted. In our series of cases, the shock dose producing coma varied from 40 to 165 units. The most common coma-producing dose was from 80 to 90 units.

A case who, during an insulin tolerance test experienced a gradual fall in blood sugar of 19 mgm. in 60 minutes to an intravenous administration of 2 units of insulin, later developed a coma on 50 units, which was complicated by a pulmonary edema. Another case, similarly tested before treatment, showed a prompt reduction in blood sugar of 33 mgm. in 15 minutes, but did not have a coma during treatment until 110 units were given.

BLOOD PRESSURE.

There has been an almost uniform rise in the systolic pressure, and some fall in the diastolic pressure to produce an increased pulse pressure during the shock period. However, on taking the blood pressure during the evening or on the rest days after the treatment has been in progress some weeks, we have been surprised to find a lowered blood pressure, and occasionally a systolic pressure between 85 and 100. In two of these cases of hypotension, we found a definite elevation of the N. P. N.

PULSE.

The tendency for little pulse change or a slight bradycardia was noticed during the early stages. After the first hour, the pulse rate has been slightly accelerated. Later in the coma stage, some change in pulse rate has been noticed, but most of the variation has been in the form of periodic acceleration. In the excitement stages, the pulse rate has been more rapid than in the other hypoglycemic states. Our findings are more in keeping with those of Müller, who found a tendency to increase in pulse rate during the shock period, while Sakel reported a bradycardia in most of his cases. Bradycardia has been observed by us, and in one case who failed to reach coma after four hours, there was a pulse rate of 44.

TEMPERATURE.

A low temperature has been a constant finding. Temperatures as low as 93.4 have been recorded, and drops to 95.+ are expected. An experience that has been repeated several times is the development of chill and subsequently fever, a short period after the interruption of a long deep coma. In one case, after a chill, the temperature rose to 104.0 F. and subsided over a period of several hours.

MOTOR EXCITEMENT.

In our cases, the excitements were only rarely associated with any overt manifestations of hunger. However, we have seen a patient eat his tooth paste during the early period of excitement. The sequence of events in our excited cases has followed closely the phases described recently by Angyal.[5]

Some patients would show excited features during the period the dose was being raised to coma-producing levels. However, some of our cases had good comas for a period of two to four weeks before showing any evidence of the excitements. It is our impression that the cases that developed severe motor excitements and tonic spasms during hypoglycemia do not show such good clinical results.

CONVULSIONS.

In our cases, convulsions were encountered in 16 per cent of cases. Usually the convulsions were preceded by twitchings and jerkings of muscle groups, but occurred without any warning, as well. In one case there was a right-sided seizure that developed after coma had been interrupted by the giving of glucose orally. We do not consider convulsions to be of unfavorable prognostic significance.

OTHER NEUROLOGIC SIGNS AND SYMPTOMS.

Although no hemiplegias were encountered, the usual assortment of neurologic signs in hypoglycemia were observed. During the different stages nystagmus, bilateral Babinski, clonus, marked pupillary variations, and areflexia have been observed.

Biochemical Observations.

Biochemistry studies were made in our cases because the induced hypoglycemia provided an excellent opportunity for observing the associated chemical changes. It was thought that the humoral changes might give additional information that would aid in interpreting behavior and offer a possible prognostic guide. Georgi,[6] in a study of the biochemical aspects of insulin shock treatment, felt that there was a certain relationship between the humoral and the behavior changes. It was his belief that the improved cases had a normal potassium calcium ratio and slight daily variation of the ratio. After conclusion of treatment, the improved cases showed a high potassium level. The cases that did not improve had a low potassium calcium ratio and a great daily variation of the ratio.

These studies were begun with a realization that a certain fogginess surrounds the biochemical status of the schizophrenic in the literature. As in the case of the biochemical reactions to insulin, there have been a variety of results reported. The impression is obtained that there may be a somewhat greater variation from the normal range in schizophrenic than in normal individuals.

SUGAR METABOLISM.

The blood sugar curves during treatment were essentially as reported by Sakel. The drop in blood sugar occurred early in the treatment, and remained at a fairly constant level during the periods of stupor, excitement or coma. Frequently, the blood sugar would rise slightly during the period of coma. During coma, the blood sugar levels would usually range from 30 to 55 mgm. per cent, although levels above and below these figures were obtained.

MINERAL METABOLISM.

A study of the mineral metabolism was undertaken by the Department of Biochemistry and carried out by a graduate student, Mr. William Osheroff, under the supervision of Dr. S. Morgulis. Because of the variation in intensity of the hypoglycemic reaction on different days, it was felt that the blood could be obtained under more nearly basal conditions when taken in the morning before administration of insulin. The blood was taken on a group of pa-

tients before treatment, during Phase I, usually on several occasions during Phase II, and occasionally during Phase IV.

Owing to a lack of funds and availability of well-trained workers in chemical analysis, a more complete study of mineral metabolism could not be made. The serum potassium, sodium, calcium, magnesium, phosphorus and chlorides were studied at the intervals stated. In all of the estimations except the chlorides, a probable error is admitted due to concentration of the serum in the hypoglycemic state.

Potassium.—Many of the blood specimens could not be used for the potassium determination, due to a very slight hemolysis which would occur in spite of great care being taken in collecting the specimen. A study of our cases to date would indicate that there is a definite tendency toward increase in the potassium during the second to ninth week of Phase II.

Sodium.—Except for two cases which showed a transient rise in the sodium during Phase II, there was little remarkable change in the sodium.

Calcium.—There seemed to be a tendency for the calcium to increase in certain cases at about the second week of Phase II.

Chlorides.—Most of the chloride readings during Phase II run at a low normal. Study of the individual cases shows a tendency for the chlorides to drop during Phase I, but particularly during Phase II.

Magnesium.—There was little significant change in the serum magnesium.

Phosphorus.—In our series there was little change, although mineral analyses done during periods of hypoglycemia revealed a low serum phosphorus.

Non-Protein Nitrogen.—Because of the tendency towards a high potassium and low chloride in the serum during the Phase II, the possibility of a reactive hypoadrenalism was considered. In certain cases, a low blood pressure of 85 to 100 systolic was found in the evenings, which supported this belief. As a result, N. P. N. determinations were run, which showed a definite elevation in two cases with a low blood pressure.

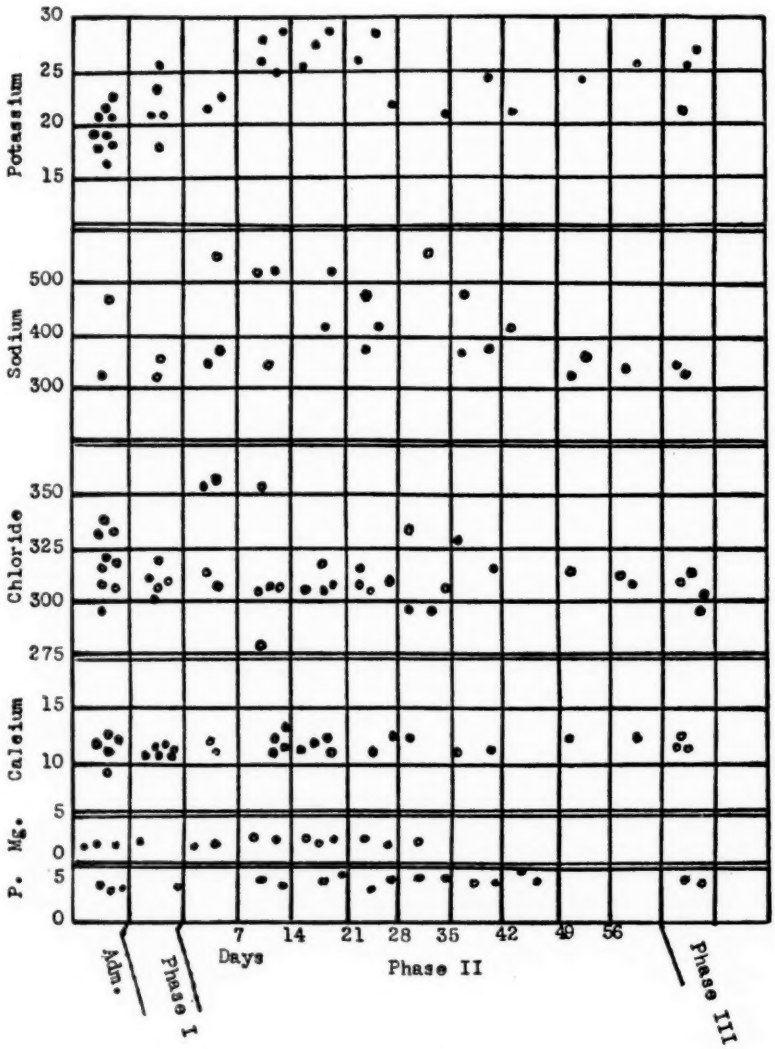

FIG. 1.—Results of Mineral Analyses on Blood Serum Taken in the Morning Before Administration of Insulin at Intervals During the Period of Treatment.

Psychobiological Reactions.

In over a half of our cases there occurred an amelioration of the psychotic features of the personality maladjustment. This was shown by the loss of delusions and hallucinatory activity, the appearance of lucidity and insight, a release of affect, and the establishment of rapport and interest. In many of the cases, these developments took place early in the treatment. This is well illustrated by the following case:

A young, single, man of 22, a government stenographer, following several years of tension over a masturbation problem, became convinced he had a remarkable ability to produce orgasms in young women at a distance. He then rationalized this power by concluding he was a reincarnated Christ, gave away his money and belongings and went to Florida to find his mission. Because of his great powers, he thought he was in danger from evil men. He was picked up in Florida and returned to Omaha. The evolution of the psychosis, through a sequence of erotic fantasy, philosophical ruminations, sexual projections, and delusions of grandeur and persecution, covered some three years, though his overt behavior disorder appeared in September, 1936. Ten days after treatment was instituted, he had his first complete coma. That afternoon, he wrote a description of his condition, showing insight. He said he had lost the idea of influencing others, and that while he remembered fully his thought of being Christ, he now realized he was mentally sick. From being restless, picking at his fingers, and smiling inappropriately, he had become friendly, talkative and cooperative. Two weeks later, Phase IV was commenced.

There are certain manifestations during the course of treatment that deserve special consideration.

Expansion of Mood.

One of the more outstanding features is expansion of mood. This may at first occur during the hypoglycemic states prior to coma or during the awakening. Before coma, it is often accompanied by marked psychomotor excitement. The patient becomes euphoric, laughs, makes facetious remarks, is jovial and talkative. During this phase, they may also relate in a carefree manner emotionally traumatic incidents that apparently have a relation to the conflicts underlying the psychosis. One married patient, while euphoric, told of a sexual perversion, cunnilingus, the attempted practice of which with his wife had signalized the onset of the psychosis. As the treatment goes on, this elevation of mood is noticeable in the

hypoglycemia free period, though in less pronounced form. We have the impression that its appearance is, on the whole, of good prognostic significance, and that it is important because it presents an opportunity for a psychotherapeutic approach to the problem.

DEPRESSION.

Depression has manifested itself during treatment in four cases in an accentuated form, after a subsidence of more clearly defined schizophrenic symptoms. The patient with a cunnilingus conflict mentioned above, who had been in a state of catatonic stupor for six months, after a period of about ten days of sociable genial activity, became depressed and experienced auditory hallucinations of admonitory type.

PREOCCUPATION WITH DEATH IDEAS.

A number of patients have expressed marked concern over ideas of death, on awakening from coma. The statement has been made frequently by patients on awakening that they had felt as though they were far away and that it would be impossible to get back. Sexual conflicts have been much in evidence in the history of these cases.

EFFECT OF TREATMENT ON EXCITEMENTS.

Catatonic excitements have been uniformly and quickly relieved by the treatment. The following case may be cited:

J. B., age 27, laborer, who had had two previous attacks (at 16 and 24 years of age, respectively, the latter requiring hospitalization for months), three days before hospitalization became abnormally quiet, abstracted and confused. The day before, he became noisy and violent. Upon admission, he was at first unresponsive and depressed, but the day after was noisy and violent. He became progressively disturbed, ill-natured, combative, destructive of bedding and clothing; would stand nude in his room; smeared his person and room walls with feces; at times would stand in one position for hours. His talk was senseless, incoherent, profane and obscene. Seven days after the beginning of his treatment he was given 100 units. There had been so far no shock and no noticeable improvement. During the resulting hypoglycemia, he became responsive to questions and told the physicians he was there because he was "nuts." Coma occurred and was repeated daily. A week later, he was quiet and cooperative, and mingling freely with the other patients.

EFFECT OF TREATMENT ON DIFFERENT REACTION TYPES.

While it is impossible to divide the schizophrenic reactions into clear-cut types, there have seemed to be some schizophrenic features that have responded more readily to this treatment than others. Our cases with features which have been classed as catatonic excitement perhaps showed the best response. The acute schizophrenic reactions with paranoid beliefs and hallucinatory activity seemed to respond well. Our cases with stupor have shown improvement, but no clear-cut remissions. Those cases which had depressive features did not seem to do well with this treatment. The cases which showed features classed chiefly as hebephrenic did not seem to be as favorably influenced as other types.

Discussion.

We believe the hypoglycemic shock method to be a type of treatment that provides an attack upon the schizophrenic problem at a physiological level, and a type of treatment that is essentially non-specific in type. Like all non-specific therapy, the treatment is efficacious when it is applied to a disease which is not fixed and chronic in nature. Where the disorder is largely acute, labile, and of an "attack" nature, then a type of non-specific therapy may be efficacious in relieving symptoms.

The physiologic changes observed appear to be those of strong parasympathetic stimulation with a compensatory sympathico-adrenal activation. In addition, we have in occasional cases observed what we believed to be a secondary hypoadrenalism during Phase III and Phase IV. The biochemical facts show suggestive changes that are of no prognostic significance to date. The changes in mineral metabolism are, in some cases during periods of rest, similar to those found in a hypoadrenalism.

Because of the integration of the individual, changes in vegetative and biochemical functioning would naturally be reflected in the higher psychobiological levels of functioning. In the majority of our cases, there has been a change in behavior, and in over half, the change has been in the form of amelioration of psychotic symptoms to the extent that they were classed as remissions.

As a result of our experience, this type of treatment appeals to us particularly in young, robust males, whose schizophrenic reac-

tion is of short duration. We feel very definitely that the treatment is dangerous in type and demands close observation. In our group of cases, the two deaths were at the Douglas County Hospital, where the opportunity for close observation is not the same as in private practice. One woman of thirty-seven, after her ninth coma on 50 units, died with a pulmonary edema that developed shortly after the termination of a coma. The second case, a man of thirty-seven, badly deteriorated, with a long-standing schizophrenic reaction, shortly after the interruption of his tenth coma, complained of severe upper abdominal pain, vomited, quickly went into a circulatory collapse and died. While there was no autopsy, the cause of death was thought to have been a coronary thrombosis. In addition to the two deaths, a woman of 42 developed a pulmonary edema on 50 units, from which she almost died. A fourth case, a young woman of 22, went into a status elipticus four hours after termination of her ninth coma. The next day she developed hyperpyrexia, 106. F, a pulse rate of 170, and pulmonary signs. Her condition responded promptly to intravenous administrations of 5 per cent glucose in normal salt. It was noted that her blood chloride checked the morning after the convulsive state was low, 275 mgm. as compared to an average of 325 mgm.

Conclusions.

Hypoglycemic shock treatment has been given to 41 schizophrenic patients since October, 1936. Thirty-one cases have completed treatment, of which there has been an amelioration of psychotic symptoms in 58 per cent.

Physiological, biochemical and psychobiological facts observed in the course of treatment are reported.

The dangers of the treatment are emphasized by the report of two deaths and serious complications in two other cases.

It is believed that this type of therapy deserves a place as an adjunct in the treatment of schizophrenia because of its ability to produce rapid change in behavior, and because of the opportunities for other types of treatment that present themselves with this change in behavior.

The hypoglycemic shock treatment seems to be more suited for robust, young males who are experiencing a schizophrenic reaction of short duration.

No attempt has been made to discuss possible mechanisms that might be responsible for the favorable behavior changes observed.

THE EFFECT OF THE HYPOGLYCEMIC THERAPY ON THE PSYCHOTIC PROCESS.

By BERNARD GLUECK, M. D.

In place of a formal paper on this important subject, I shall confine my remarks to a brief consideration of two aspects of the question we have been discussing this morning. The first of these concerns one of the immediate and direct effects of the hypoglycemic therapy on the psychotic process or state. While what I have to say is in the nature of a clinical impression and not the result of any deliberate research, it is based upon the clinical observation of a fairly large number of cases treated by others and of 32 patients treated at Stony Lodge under my personal supervision.

Now, neither by nature nor by training or experience am I to be classed as a technical research or laboratory worker. For a considerable number of years now I have been active in the field of psychiatry as clinician and therapist, and have depended for carrying on this work to a very large extent on such equipment as is embraced within my own personality. I work in a setting of a small private hospital, well equipped for dealing with mental disorders but essentially depending upon techniques which might be termed interpersonal relationships in which one human being attempts to influence another human being's health and behavior. Now it is a well-known fact that this type of procedure is commonly hampered and interfered with by certain attitudes and reactions in our patients which render a helpful interpersonal relationship difficult or impossible. I am referring to patients' tendencies to isolation and withdrawal, to reactions of antagonism and resentment, to the anxieties, fears and delusional complexities which render these people inaccessible to the kind of relationship between patient and physician which is indispensable for a helpful therapeutic approach. The thing that has impressed me most deeply and most dramatically at times about the insulin therapy is its direct and frequently very rapid effect upon the patient with respect to these attitudes of isolation, aversion and suspicion. What is technically termed a transference capacity is, at times,

released in a most convincing and dramatic manner very soon after the introduction of the insulin therapy, rendering patients who had hitherto been utterly inaccessible to any psychological influence, quite approachable and capable of benefiting from the various services which the hospital offers.

For very definite reasons I do not wish to speak of ultimate results, but these immediate effects upon the psychological attitudes of the patients cannot be overstressed.

Another significant and very impressive manifestation of a psychological nature is to be observed frequently at the time when the patients are entering upon a state of remission. It is most impressive to note how some of the patients struggle against the necessity of getting well; how they resist and resent the force which is driving them towards a greater recognition of reality and an adjustment to its demands. Sometimes this resentment is very clearly and unmistakably expressed in the patients' insistence that they do not wish to get well; that they never asked to be made well; that they want to remain ill just as they were, etc. Occasionally this reaction to a pull towards an unwished for recovery is reflected in a profound emotional depression, sometimes accompanied by a rather intense suicidal drive.

As one's experience with the effects of the hypoglycemic therapy increases, one comes to doubt increasingly the validity of many of our notions concerning the question of deterioration in dementia præcox. We have already observed quite a number of manifestations which have been considered in the past as irreversible end-phenomena of a deteriorating process, entirely disappear and leave no trace of any sort behind them. On the other hand, impressive as is the psychological aspect in connection with the insulin therapy, patients are observed in whom no need whatsoever exists for any kind of aid to recovery outside of the actual effect of the hypoglycemic state.

Thus, one very excited catatonic boy recovered completely, and has been well now for several months, after only three insulin shocks. On a former sojourn in the hospital, some three years ago, with a similar condition, it took a number of months before a remission was attained.

But it would be entirely fallacious to assume that either the physiological effect of the insulin therapy, or the improved oppor-

tunity for psychological therapy which this effect brings with it tells the entire story as regards the nature of the forces at work in this therapy. More so even than formerly, experience with the insulin therapy has demonstrated the great significance for the destiny of the schizophrenic of his hereditary background and so-called constitutional make-up. Perhaps in the final analysis, this is still the most determining factor, since the outcome of the struggle between the forces which pull the patient in the direction of illness, and those which as result of the therapy force him to an emergence from the illness, depends in the final analysis upon the individual's capacity for mastering instinct and impulse on the one hand, and environmental life vicissitudes on the other hand. Of great significance also are the conditions under which the patient is obliged to work out his convalescence. Recovery from a biochemical approach ordinarily takes place without an adequate personal preparation of the patient for such an event, in contrast to what takes place in connection with the psychological form of therapy. The patient, therefore, is much more vulnerable to certain deleterious influences than he would be if he had been gradually prepared to meet the issues of a normal life. Some of the relapses which we have encountered might definitely have been avoided had not our enthusiasm over the recovery of a patient who had been given up as hopeless led us to an unjustifiable degree of indifference concerning the conditions of the patient's convalescence.

So much for the clinical aspects of this question.

I would like to have permission to refer briefly to the Round Table Session of last evening, which was exceedingly well attended by an enthusiastic body of our membership. It was clearly demonstrated at this meeting that there is a great need for some central source of reliable information concerning the nature and technical details of this mode of approach, and while the active participation in this movement by the New York State Department of Mental Hygiene has helped materially in this direction, it was suggested by many that The American Psychiatric Association might help to organize some sort of nucleus from which this information might issue.

THE PROBLEM OF INSULIN SHOCK.

By HENRY J. JOHN, M. D., Cleveland, Ohio.

The problem of insulin shock in the treatment of schizophrenia has made us clinicians dig out some of our old studies and observations in an attempt to elucidate and evaluate the problem from purely clinical and laboratory angles. As I have listened to the excellent papers given here, many of my former observations and data came to my mind, for the study of blood sugars under various conditions has interested me intensely for the past sixteen years.

Drs. Kepler and Moersch have given an excellent classification of the hypoglycemias. I shall try to illustrate some examples of these groups from my old records.

The question of induced hypoglycemia I reported 12 years ago, in 1925, at which time I attempted to call attention to a syndrome simulating hyperthyroidism which was due merely to a continued overdosage of insulin. I gave it the name of hyperinsulinism at that time merely to emphasize it. Briefly the story was as follows: A man 38 years of age was told he had diabetes when glycosuria was found at life insurance examination. He was immediately overdosed with insulin and developed signs of nervousness and tachycardia which were interpreted by his physician as a condition of hyperthyroidism. He was sent in for thyroidectomy. I found him not to be diabetic, took the insulin away and the symptoms subsided.

Insulin then was a new gadget and I was anxious to impress on the profession the fact that an overdosage over a long period of time can create a picture resembling hyperthyroidism.

In 1927 I reported a similar case in a surgical journal. This case also was getting too much insulin when no insulin was needed and he had the classical symptoms simulating the picture of hyperthyroidism. In fact this man had already had two ligations done before I saw him. At this time I began to feel quite keenly about arousing the surgical profession to this picture since such cases were not being sent to the internist but to the surgeon for thyroidectomy.

EXCESSIVE INSULIN-NO REACTIONS.

CHART I.

However, not every case receiving an overdose of insulin will manifest insulin reactions. In Chart 1 I drew graphically the data on a man 42 years of age who, when I first saw him, was taking 170 units of insulin a day, never had a reaction, when he actually needed but 20 units a day as you see from the chart.

Another patient about 50 years of age, whom I discharged on 20 units of insulin twice a day, was taking by mistake 200 units twice a day for a whole month, was in a constant reaction and at the end of the month all insulin was discontinued.

Or in the case of a little girl five years of age, whom I gave 100 units of insulin intravenously in the morning and 100 units intravenously in the evening for a whole month, and during that time she had no reaction and her blood sugar did not drop to a particularly low level.

We can induce hypoglycemic reaction often by a large dose of insulin but frequently a large dose will not elicit such symptoms. There must be a marked individual variation in different people, for I have seen patients very sensitive to an increase of but two units.

Insulin reaction does not always occur during a state of hypoglycemia. I have seen reactions with a blood sugar as high as 360 mg. per cent. These are exceptions, of course, but they do occur.

The first time I learned what an insulin reaction was like was in 1921 when I was doing a series of glucose tolerance tests on myself studying the stability of the curve. Chart 2 shows that in one of these tests, at the third hour, my blood sugar dropped to 35 mg. per cent at which time, as I looked at my original notes, I had put down: (1) Feeling of fainting away; (2) Extreme hunger; (3) Marked perspiration; which are the cardinal symptoms of hypoglycemia. This is a physiological type of hypoglycemia.

In true hyperinsulinism where we deal with a condition of a tumor of the islands or else their hypertrophy, I feel that it is only surgery which helps. But this is the only surgical group in the lot. In 1931 I reported a case of a physician 61 years of age who had diabetes, hyperthyroidism, cirrhosis of the liver. In five months I could discontinue all insulin and a year later he died following a hypoglycemic shock. At post mortem we found a hypertrophy of the islands.

A hepatogenous type of hypoglycemia I have not seen or else failed to recognize, but a hypoglycemia due to destruction of adrenals you can follow from Chart 3. This was a young man 20 years of age with hyperthyroidism and diabetes. It took 60 units of insulin a day to keep his blood sugar level around 200. There was a marked drop of blood sugar following the first denervation but it came up quickly. When he had the second denervation of

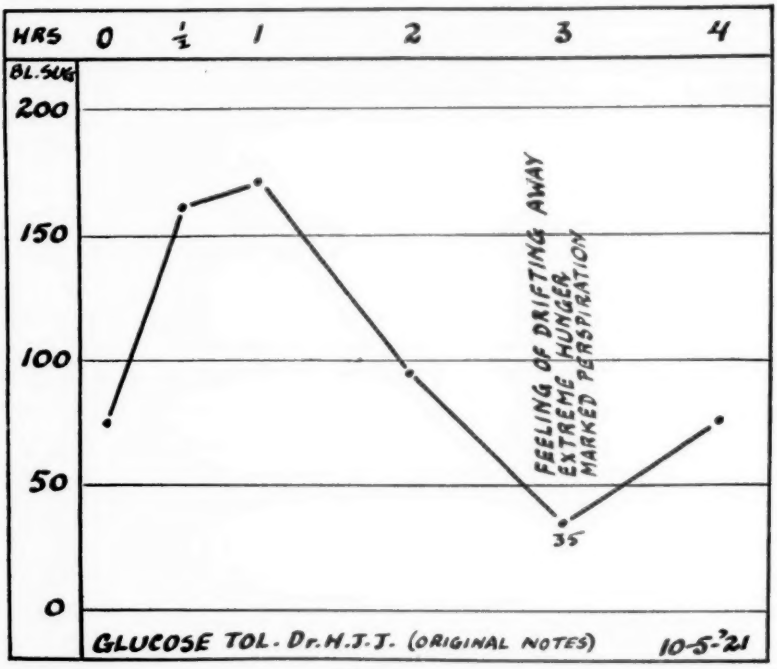

CHART 2.

adrenals five weeks later there followed an abrupt drop of blood sugar and the man died. A post mortem cleared up the picture for the first adrenal was completely fibrosed, thus inactive, and the second adrenal had acute hemorrhagic necrosis which put it out of function and you can see how the blood sugar level was changed thereby.

We also see occasionally a condition which resembles petit mal from over-dosage of insulin which clears up when insulin is properly adjusted and hypoglycemia eliminated.

There are many people who carry a marked hypoglycemia and have no symptoms. In 1928 in my enthusiasm to call attention to this fact I analyzed 22,808 blood sugars taken on patients during routine examination, all below 120 mg. per cent. I was anxious to show that a blood sugar below 60 in a nondiabetic was not as rare a finding as it was thought to be. Over 200 were below 60, some

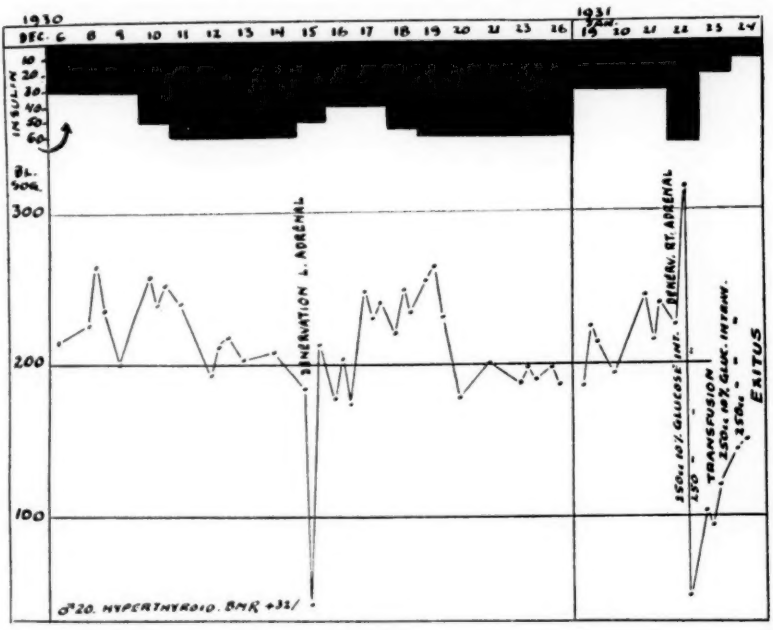

CHART 3.

of them as low as 30 mg. per cent without symptoms of hypoglycemia.

I have brought out some of these facts merely to emphasize what had already been said. Some years ago, in 1930, I had what seemed to me a typical case of hyperinsulinism or rather chronic hypoglycemia, with nervousness, sweating, loss of weight, weakness and even spells of unconsciousness. Her blood sugar level ranged between 47 and 84 at meal times, and it was probably considerably lower between times. I conceived the idea of treating her with insulin, 10 units three times a day half an hour after meals in an

attempt to give the pancreas a " physiological rest." And the result was a most remarkable and quick improvement and finally a complete cure with a heightening of the blood sugar level. Since then I have employed this method at least a dozen times with good results.

Now all this discussion leads us to realize that there is a tremendous variation in individuals. To give a five-year old child 100 units of insulin intravenously morning and evening for a whole month and have no reactions and then to produce a reaction by a mere increase of two units in a grown up shows what a tremendous difference there is in an insulin-reaction-threshold in various people. This you will meet with I am sure in the group of cases of schizophrenia you are treating. There cannot be a hard and fast rule as to the dosage, a fact which has been already pointed out. Each case has to be evaluated on its own merits. The thing which impresses me tremendously is the relatively good result obtained in this therapy.

I can't discuss your results. They speak for themselves. To salvage large numbers of human beings who thus far were lost to the world is an achievement before which even the greatest skeptic must bow in reverence. The risk is apparently not great as the low mortality indicates. But were it 10 times as high it would still be a great achievement. I feel that Dr. Sakel and the men who worked with him have done a truly fine piece of pioneer work and have shown the way. Time, energy, care and enthusiasm, tempered by judgment of hundreds of others should clear up the byways and perhaps simplify the procedure in time, for all great achievements in their final analysis are reduced to simple procedures.

DISCUSSION ON HYPOGLYCEMIA SYMPOSIUM.

DR. JULIUS STEINFELD (Peoria, Ill.).—In Dr. Michell's institution, during the past nine months, I have treated (in collaboration with Dr. Burton) eighteen cases. Sixteen were schizophrenics, two manic-depressive. Six of the sixteen schizophrenics have been discharged with four of them showing full recovery, two were greatly improved. If the remaining ten cases, two are about to be discharged. Cases having recurrent attacks, even over a period of years, show better results than those constantly ill for shorter periods. We rather prefer giving larger doses of insulin for shorter hypoglycemic periods, than smaller doses for longer periods because our experience shows that the latter is more exhausting and dangerous for the patient. On some patients who did not show the desired response to insulin, sudden changes were obtained after convulsions produced either by insulin or metrazol.

DR. G. HEILBRUNN (Elgin, Ill.).—The treatment has just been completed on a group of 13 patients in Elgin State Hospital. There were 8 cases of a duration up to 1 year, 6 of them were paroled home, 1 showed marked improvement and 1 did not improve at all. Five had a duration of between 4 and 8 years, 1 has shown improvement while the other 4 remained unchanged. I found from my experience in Switzerland that 70 per cent of the patients showed such a sensitization to insulin that the initial shock dose could be reduced by an average of 40 per cent. A decrease of the blood sugar level below 60 mg. per cent seems to be necessary for the development of a clinical reaction. The appearance of severe hypoglycemic symptoms has been found to be a function of the rapid decrease of the blood sugar, requiring an average of 60 minutes, and the maintenance of a level of 30 mg. per cent or lower for at least an average of an additional 60 minutes. The sedimentation rate of erythrocytes remains approximately the same; the potassium level decreases but shows an elevation in the passing weeks. Calcium exhibits less variations. Cholesterol shows an elevation and lowering without any relation to the clinical picture. Electrocardiographic readings showed arrhythmias of minor significance, lowering of ST, flattening and sometimes negativity of the T wave, widening of the Q. R. S. and occasional appearance of U waves. All heart changes are reversible, however. Three patients had two epileptic seizures each, without any therapeutic influence one way or the other. We did not interrupt the seizure with adrenalin or intravenous glucose. We allowed the seizure to proceed, and when the patient was relaxed, he was fed through the nasal tube in the usual manner.

PRESIDENT CAMPBELL.—In view of the late hour, there will be no general discussion, but I should like to give Dr. Sakel an opportunity to sum up, or to make any comments on anything that has been offered.

DR. MANFRED SAKEL (closing).—I have a few words about the epileptic seizure, because I consider it very important. Certainly the danger of epileptic seizure was a little bit overestimated, but only a little, and it depends on the time when the patient went into an epileptic seizure. We have two kinds of epileptic seizure during hypoglycemia. The first is in the so-called dry shock. It appears about an hour or a half hour or two hours after giving the glucose. This is only one kind of reaction of the patient—this epileptic seizure is not a dangerous one and you can wait a few minutes and terminate it with a nasal tube. It is better if you don't give adrenalin, because I don't like to give it in most cases. If the epileptic seizure happens after three or four hours and happens after the patient is in coma, it is a signal of danger. This second type of epileptic seizure is very dangerous and I would regard it as an indication to terminate with intravenous glucose at once.

The first, so-called dry shock, is not so bad, but the second is a sign that the patient has achieved the greatest possible border of danger.

PRESIDENT CAMPBELL.—I should like to thank you, Dr. Sakel, formally in the name of The American Psychiatric Association for having come before us to present your recent work which has such a very great interest for us and such a great importance for our patients.

This terminates the formal scientific session.

THE ELECTRENCEPHALOGRAM OF SCHIZOPHRENICS DURING INSULIN TREATMENTS.

THE "DELTA INDEX" AS A CLINICAL MEASURE.*

BY HUDSON HOAGLAND, PH. D., D. EWEN CAMERON, M. B., AND MORTON A. RUBIN, PH. D.,

Worcester, Mass.

INTRODUCTION.

In another paper[1] we described the behavior of electrencephalograms during individual insulin treatments of schizophrenics (see also (2)). A new measure of waves longer than alpha waves of the electrencephalogram, called the "delta index," was devised and studied as a function of blood sugar and alpha wave frequency (Berger rhythm) during insulinization and recovery. Our electrencephalograms have been recorded with a resistance-coupled amplifier and ink-writing undulator on paper tape. The electrodes were wires attached to lead pellets 2 to 3 mm. in diameter, the pellets making contact with the scalp through electrode paste and held in position by collodion. The grid electrode was placed over the occiput, 2 cm. above the inion, and an "indifferent" electrode was attached to the skin behind each ear, parallel leads from these last attachments being brought together to form a common connection. Our tape speed has been 27 mm. per sec., our amplification 10 microvolts = 1.5 mm. and our "time constant" 0.2 sec. (but see (1) for the effect of line impedance on our amplification standard).

The delta index is obtained by selecting a "typical" 100 cm. length sample of tape and, within this length of record, drawing a line through the mid-regions of *all* waves equal to or less than the

* From the Biological Laboratories, Clark University, and the Research Service of the Worcester State Hospital.

This work has been aided in part by a grant from the Rockefeller Foundation.

We are indebted to the Lillie Co. for generous supplies of insulin used in treating our patients.

characteristic alpha waves in duration. The pencil line is run *over* crests and troughs of all waves longer than alphas (*i. e.*, in general, all waves greater than 0.1 sec. in duration). The resulting curving line (see Fig. 3 of (1) and also Fig. 3 of this paper) is then measured with a map measurer and the difference in cm. between the length of the curved line, as read from the measurer, and 100 cm. is defined as the delta index. The delta index, in cm. per cent, is a function of the excess voltage produced by all waves longer than alpha waves. Students of the electrencephalogram have observed that sleep, anæsthesia, and other conditions of impaired consciousness result in the augmentation of what might be referred to as "base line wobble" caused by an increased number of slow, more or less random waves.[3] Walter [3a] has found a predominance of these slow waves associated with brain tumors and he has called them delta waves. It is essentially this slow wave excess, producing a disintegrated or broken-up appearance of the record, which the delta index empirically measures. In general, the delta index is referred to for convenience as the D. I. We have observed that not only does the D. I. move more or less reciprocally with blood sugar during insulin treatments but that (a) it is usually less after a treatment than before and (b) untreated schizophrenics tend, on the *average*, to show slightly higher D. I.'s than do other persons.

In the present paper we shall first consider the electrencephalogram as a clinical means of assessing the value of a given treatment. We shall then compare D. I.'s in untreated schizophrenics and in normals and then pass on to what is probably the most interesting aspect of the work, the use of the D. I. as a quantitative measure of an individual patient's condition from day to day and week to week.

Clinical Applications of the Electrencephalogram.

In the insulin treatment of schizophrenia an objective measure of progress is important on two counts. The first consists in the fact that the condition of the patient during hypoglycemia is difficult to assess on the basis of simple clinical observation. The second is the difficulty of estimating in a given patient from day to day the comparative severity of the schizophrenic reaction

itself. The electrencephalogram, and in particular the D. I., has yielded considerable objective information in the following situations:

(*a*) *During Actual Hypoglycemia.*—In the course of any given insulin treatment the question occasionally arises whether the patient, after several hours' treatment, is going to progress on into coma or whether there is likely to be a spontaneous recovery from hypoglycemia. We have repeatedly found that the "broken-up" appearance of the record decreases and, less conspicuously, the alpha frequency rises prior to remissions from coma. This applies both to spontaneous remissions (*cf.* Fig. 4 of Hoagland, Rubin and Cameron [1]) and also to remissions produced by injected sugar. These oscillogram changes occur often minutes before clinical signs indicate that the patient is beginning to recover from hypoglycemia. Since one of the most important principles of insulin treatment consists in correct assessment of the patient's condition at the time of interruption, we have found these observations of value. We have not, however, been able to gauge the actual depth of coma from the appearance of the record save to a degree which is rather rougher than that attained by examination of his pupillary and tendon reflexes. In general, it may be said that the record tends to become rather more broken-up the deeper the coma. The broken-up appearance, however, begins to show often as long as an hour before coma can be considered present clinically. We had hoped that the electrencephalogram could provide us with a means of detecting the imminence of convulsive seizures. Unfortunately we have never happened to be taking records while seizures occurred. We have, however, frequently taken records during the clonic jerking which frequently precedes the onset of coma. Since the actual hypoglycemic seizures are almost invariably preceded by these clonic jerkings and often indeed appear to be simply a marked intensification of them, we have been particularly interested to note whether the "spike and wave" formation described by Gibbs, Davis and Lennox [3] as associated with the seizures of *petit-mal* epilepsy could be detected during these clonic jerkings. We have been unable to recognize them in our records, although with our occipital lead they may well have been missed. The phenomena may be basically of a

different nature from *petit-mal* epilepsy. We have not found any qualitatively characteristic wave forms in schizophrenics.

(*b*) *As a Means of Assessing the Value of a Given Treatment.*—The electrencephalogram shows a most striking change within a short period after the termination of a treatment. Irregularities are usually much reduced. This, as estimated in terms of the D. I., can readily be seen from Table 1. The three patients whose indices are recorded there usually showed marked clinical improvement at such times, *i. e.*, immediately after insulin treatment. The D. I. values tend to rise again throughout the course of the day, and may return to their former level. Should the patient be progressing favorably, the pre-insulin index is progressively lowered by successive treatments. This will be shown in more detail later in Table 3. The three patients whose data are recorded in Table 1 were chronic cases and only one (R. W.) has been able to return home on visit. Of 35 pairs of factors taken before and after treatments, 30 showed post-treatment reduction; 23 typical pairs are shown in Table 1. This post-sugar reduction is not due to the type of occasional electrode failure previously reported.[1] The copious perspiring of the patients during treatment evidently facilitates satisfactory electrode contact. In the cases of all subsequent indices to be described in this paper only one record has been made for an electrode placement, the operation requiring only about five minutes, so that there can be no question of complications arising from the possible electrode failure earlier considered.

One of the greatest difficulties of the insulin treatment is that the type of treatment—whether deep or superficial coma, whether early interruption in the state of somnolence, or whether interruption during activation—has to be carefully adapted to the individual patient's condition and, moreover, must be varied as the patient's condition changes. The estimation of the D. I. before and after treatment seems likely to be of considerable assistance as a guide to the most desirable form of treatment.

(*c*) *Delta Indices of Normals and of Patients.*—Table 2 shows D. I.'s for different classes of subjects. Only one index is shown for each person.

From this table several things are apparent. In the first place we cannot say that a person with a high D. I. is schizophrenic

TABLE 1.

although it is true that our schizophrenics tend to average higher factors than others. Nor can we say that low indices mean that a person is not schizophrenic. A significant observation about the schizophrenics is that the patients who seem to be well adjusted to their psychoses, parole patients, long resident in the hospital who have made good institutional adjustments, and also certain catatonics who are quite unresponsive to the environment have, by and large, the lowest D. I.'s of the schizophrenic group. One

TABLE 2.

DELTA INDICES FOR DIFFERENT CLASSES OF SUBJECTS.

		Means.	Extremes.
37 normals	0.5, 0.5, 0.6, 0.7, 0.8, 0.8, 1.0, 1.0, 1.0, 1.0, 1.0, 1.0, 1.0, 1.3, 1.3, 1.4, 1.5, 1.5, 2.0, 2.1, 2.2, 2.3, 2.3, 2.4, 2.4, 2.4, 2.5, 2.6, 2.9, 3.0, 3.0, 3.0, 3.2, 5.0, 6.0, 11.0.	2.1	0.5–11.0

of the catatonics (H. H.) is an exception to this since he gives the highest indices we have encountered (*cf.* Table 1). This patient, however, is not a typical catatonic since he seems always in a state of anxiety and tension. He is considered catatonic since he refuses to speak or otherwise positively to respond to his environment except sometimes immediately after treatment. His high pre-insulin index may be due, in part, to an occasional tic, although the tic gives a characteristic wave form on the record and we have endeavored to eliminate it in measuring his D. I.

One of our patients (J. C.) occasionally, without warning, goes into a stuporous condition. The stupor is very pronounced with

eyes staring and with copious drooling. We have recorded indices from him on two occasions prior to stupor and again 10-15 minutes later during stupor. The electrencephalogram shows a striking change with the advent of stupor. Not only does the D. I. *decrease* but the alpha wave voltages *increase* from about 20 μv to 40-50 μv. Moreover, the percentage of the time that alpha waves are present also increases markedly in stupor. On one occasion the D. I. fell with stupor from 3.4 cm. to 1.5 cm. On another occasion the change was from 3.0 cm. to 0.5 cm. It should be noted that the index decreases despite increases in alpha potentials. This decrease in D. I. with changing symptoms is of interest in connection with the low D. I.'s usually found in the catatonic patients.

(*d*) *The D. I. as a Means of Estimating the Course of the Psychosis.*—From the data of Table 2 it might at first seem that the D. I. is of comparatively little diagnostic significance. However, if its limitations as an absolute measure are borne in mind, its *relative* change has been found to be very useful as a measure of the state of a *given individual patient's* psychosis from day to day. Since the index is usually greatly reduced after an insulin treatment (*cf.* Table 1) it is possible to know how low a particular patient's index may become, and it is reasonable to suppose that if the index can be forced down and held for a period of time that a parallel improvement in symptoms might be found to be correlated with the reduced value. That this is indeed the case is shown by our clinical data. It should be borne in mind that most psychotics coming to the psychiatrist for diagnosis are not "well adjusted" to their conditions. With new cases of this kind, extremely rare in state hospitals, the size of the factor may later prove to have diagnostic significance in comparing patients and normal persons.

The situation is somewhat analogous to heart-beat frequency (pulse) in man as a diagnostic index. Von Körösy, cited by Loeb,[4] found variations from 48 to 108 beats per minute in pulse frequencies in normal resting man. This does not, however, preclude relative changes in pulse rate for a given individual from being diagnostically valuable despite the fact that a 100 per cent rise in pulse rate for a man with a normal resting pulse of 50 would still be less than the unaccelerated pulse of a person with a resting value of 108 beats per minute.

Table 3 shows behavior of indices of patients on medication over periods of time and their correlation with independent qualitative clinical reports. In this table the D. I.'s were always taken some 15 hours after the previous insulin treatments. They are thus pre-insulin indices in the sense used in Table 1, *i. e.*, indices taken prior to a treatment that may be given the day of the recording. The indices have been obtained from each of some 13 patients approximately once a week. It will be seen that the weekly records follow quite well the clinical report on the patient's condition. To save space, clinical comments have been reduced to a minimum and 8 cases out of 13 have been selected for the table. It is unfortunate that the quantitative index must be compared to an entirely qualitative clinical statement but this is necessitated by the nature of schizophrenia. Comments such as better, worse, etc., are comparative with respect to the patient's condition at the time of previous date recorded in the table. Unless otherwise stated, patients were being treated five days per week.

In forming the clinical reports it was kept in mind that one of the major objectives was to investigate the possibilities of the D. I. as a practical clinical aid. Consequently the reports were based upon the series of data which the clinical psychiatrist utilizes in forming his judgment as to the progress of patients. Each patient was observed over several hours each day and, following on treatment, was interviewed. At the interview no searching analysis of the content of symptoms was made, as this in our experience has tended to produce relapse. The actual presence and, where possible, the intensity of the symptoms was checked, and in addition the patient's affective response, his capacity to mix with others, his work output, his care of his personal appearance, and his sex activity were all taken into account. In addition the psychiatrist's observations were checked against the daily reports from the nurses and against the periodic reports from the Occupational Therapy Department. The relatives were also interviewed at regular intervals, and their statements utilized to amplify the final judgment.

For all but one patient in the table there is good agreement between D. I. and clinical report. In this case (T. S.) there were no clinical criteria to compare with the factor, which seemed to

TABLE 3.

CORRELATION BETWEEN EXCESS FACTORS AND PROGRESS OF THE PSYCHOSIS.

PATIENT (A. S.) HEBEPHRENIC. TWO YEARS DURATION.

Date.	D. I. (cm.).	Clinical comment.
Nov. 27	15.0	From 27th at first steady improvement.
Dec. 3	12.0	Less excitement, better attending and social orientation.
11	5.5	
23	3.6	Steady improvement.
31	3.1	Steady improvement.
Jan. 6	2.2	Steady improvement.
15	3.1	Steady improvement.
21	12.3	Spontaneous relapse, worse.
29	3.0	Again improving.
Feb. 3	4.0	Better, and gaining weight.
10	12.0	Definitely worse.
19	9.0	Not doing well. Between 19th and 20th improved. Relapse on 22d.
23	9.1	About same as on 19th.

PATIENT (C. A.) INDETERMINATE. TWELVE YEARS DURATION.

Date.	D. I. (cm.).	Clinical comment.
Jan. 22	9.5	Slightly worse 22d to 27th.
28	12.0	Unchanged.
Feb. 4	12.0	Unchanged. More irritable and unpleasant than before treatments.
9	10.8	Unchanged.
19	6.8	Much improved.
24	2.0	Continued improvement
Mar. 1		Taken off treatment.

TABLE 3—CONTINUED.

PATIENT (E. B.) HEBEPHRENIC. FOUR YEARS DURATION.

Date.	D. I. (cm.).	Clinical comment.
Nov. 9	24.3	Considerable improvement to Dec. 10, then plateau in
13	10.9	symptoms, no further progress for some days.
28	4.2	
Dec. 3	4.1	
9	4.2	
19	2.2	Mild slump Dec. 10-21.
23	0.9	Better; home for Christmas.
31	2.6	Clinically worse.
Jan. 7	2.9	Slightly better.
9	4.8	Some relapse.
15	8.0	Some further relapse. On 22d, more irritable.
25	9.0	Not so well, relapse.
28	1.5	About same.
Feb. 1	7.0	About same.
3	2.0	About same.
8	3.1	Improved.

PATIENT (J. C.) CATATONIC. SIX MONTHS DURATION.

Date.	D. I. (cm.).	Clinical comment.
Dec. 15	5.1	By 22d much improved.
23	2.4	
Jan. 2	3.9	Influenza; treatments stopped 3d to 9th.
8	13.0	Much worse.
15	3.0	Better.
28	3.4	Slight relapse.
Feb. 3	3.0	Slight improvement.

TABLE 3—CONTINUED.

PATIENT (G. N.) EXCITED CATATONIC. SIX MONTHS DURATION.

Date.	D. I. (cm.).	Clinical comment.
Oct. 14	6.4	Steady improvement with relapse Dec. 9 to 12. Transfer
Nov. 24	6.2	to disturbed ward.
Dec. 9	3.1	
19	2.3	Told if behave, home for Christmas.
23	0.6	Further improvement.
31	2.7	Definite relapse.
Jan. 9	5.0	Jan. 4 and 5 suicidal, worse.
15	4.0	Very bad, *taken off* treatment.
18	4.0	Same.
21	4.7	Same.
25	2.0	Same.
28	4.0	A little better than 25th.
Feb. 1	4.0	Unchanged.
4	3.0	Unchanged.
9	4.2	Unchanged.
15	2.3	Family says he's improved but he is still off treatment.

PATIENT (T. S.) CATATONIC. ONE YEAR DURATION.

Date.	D. I. (cm.).	Clinical comment.
Oct. 14	5.1	No improvement at all with treatments.
Nov. 2	4.1	
4	4.1	He broods much, never speaks. D. I. varies considerably
6	17.1	but when low symptoms unchanged.
20	16.0	
28	6.2	
Dec. 3	4.2	
12	0.3	Though mute, does not appear to be completely out of
15	2.0	touch with surroundings but usually indifferent to
24	1.7	them.
31	2.8	
Jan. 7	2.0	
8	2.5	
16	18.6	
21	1.5	
28	1.0	

TABLE 3—CONTINUED.

PATIENT (A. C.) PARANOID. THREE MONTHS DURATION.

Date.	D. I. (cm.).	Clinical comment.
Jan. 15	11.2	Improves steadily until 25th, then some relapse followed by improvement to Feb. 9, then again a relapse between 9th and 23d.
22	5.5	
28	2.0	
Feb. 4	3.2	
9	3.3	
23	3.8	

PATIENT (T. G.) INDETERMINATE. MANY YEARS DURATION.

Date.	D. I. (cm.).	Clinical comment.
Nov. 2	17.0	Had been treated for some weeks prior to this.
3	10.0	
4	4.0	Cheerful and euphoric.
6	7.0	Improved.
9	2.5	Improved.
13	7.9	Some relapse, noisy and aggressive.
16	20.5	Definite slump, dull, uninterested.
17	4.1	Less dull, but less interested than when at his best.
18	6.1	
20	3.5	Quiet and subdued.
Dec. 9	2.6	Definitely better.
19	4.8	Taken off treatment.
31	4.8	Remains clinically about same until first week in February when has definite relapse followed by some spontaneous recovery. Lost 8 pounds between Jan. 15 and 25. By 19th 10 pounds underweight.
Jan. 8	4.9	
16	8.6	
21	5.5	
28	4.0	
Feb. 3	12.0	
9	3.5	
19	3.0	

fluctuate in a more or less random manner, often attaining surprisingly low values. In all, from the remaining 7 patients there have been obtained 84 D. I.'s. Of these 74, or 88 per cent, show good correspondence with clinical reports, *i. e.*, when a patient is recorded as better the index decreases, when worse, it increases. Indices for two of the patients show 100 per cent correspondence with clinical reports. Steady values occur when the patients sometimes show a plateau. Two patients not included in Table 4 have been difficult to follow clinically owing to considerable shyness and passivity. In one case (R. W., a catatonic) 18 out of 26, or 70 per cent, D. I.'s correspond fairly well with clinical reports. In another even more introverted and unresponsive patient (E. T.) the agreement holds in 9 out of 15, or 60 per cent, of the cases. Like T. S. in Table 4, none of these patients has shown the sharp behavioral contrasts manifested by the 7 other patients. Three other patients, making our total of 13, started with low indices (2-4 cm.) which remained low throughout the series of treatments. It was, therefore, not possible to use the D. I. as a measure with these patients. After a few weeks we ceased to record their D. I.'s.

The fact that 12 per cent of the indices for the 7 patients do not conform to the clinical picture, and that larger percentages for two others do not so conform, we believe may be due to three reasons. In the first place, qualitative estimations of a patient's gross behavior are subject to obvious limitations as criteria of degrees of psychosis. These limitations are especially pronounced with patient T. S. of Table 3, and with R. W., and E. T. not in the table. We believe we have eliminated our own subjective bias as much as possible by having one of us (R. or H.) obtain the electrencephalogram, seeing the patient only in the observation room during the test, and having another of us (C.) formulate entirely separately, without seeing the electrencephalogram, the clinical behavior report. Comparisons of D. I. and behavior report were made only about once a month. In one case, C. A., comparisons were made only at the termination of the series of treatments. A second source of discrepancy in Table 3 is the fact that changes in D. I. may actually precede changes in overt behavior of the patient. The third, and perhaps the most obvious, source of discrepancy between index and clinical report is the fact that there may be hour-to-hour spontaneous variations of several cm. in patients' D. I.'s, as

may be seen from the tables in our first paper.[1] The factor is fairly stable in most patients but in some the variations may produce a considerable error if only occasional progress records are used for samples.

(*e*) *As an Index of Changes Which Cannot Yet be Picked Up Clinically.*—We have some evidence that changes in the patient may be detected by the electrencephalogram before they are clinically apparent. It must be borne in mind, of course, that clinical improvement under insulin treatment may be either sudden, as after a particularly favorable treatment, or gradual, over a period of days. Similarly, a relapse may occur rapidly following upon, for example, a discussion of painful topics, or it may occur insidiously over several days. It is primarily to the gradual changes that we refer when we say that the electrencephalogram appears to give early warning of the occurrence of change. For example, in Table 3 it will be noted that the D. I. of E. B. remained at approximately 4.0 cm. from November 28 to December 9. The clinical report notes a plateau in symptoms only at the end of this period. Again, on February 3, E. B. was reported as about the same as he had been on January 25 with a D. I. of 9.0 cm. The D. I. of 2.0 cm. on February 3 appears to presage the improvement later reported on February 8, although the low value of 1.5 on January 28 had no prognostic significance. On January 29 and on February 3 the D. I.'s of A. S. were 3.4 and 4.0 cm. respectively. On February 10 the value was 12.0, the clinical report noting a relapse only at this time. It is possible that the setback began earlier, around February 3 when the factor increased to 4.0. From January 28 to February 9 C. A. was reported as "unchanged" although his D. I. on February 9 had decreased from 12.0 to 10.8, possibly a significant amount. Later there was progressive improvement, with his factor falling to 6.8 and then to 2.0. Here again it is possible that the initial fall from 12.0 to 10.8 heralded the improvement. The case of C. A. is especially interesting since all of his records were taken by Rubin and brought to the Clark laboratory to be analyzed by Hoagland who did not know the patient at all. Comparisons of his D. I. and clinical record, the latter kept as usual entirely by Cameron, were made only after completion of the series of treatments. Fig. 1 shows typical oscillograms of this patient for the series of dates recorded in Table 3.

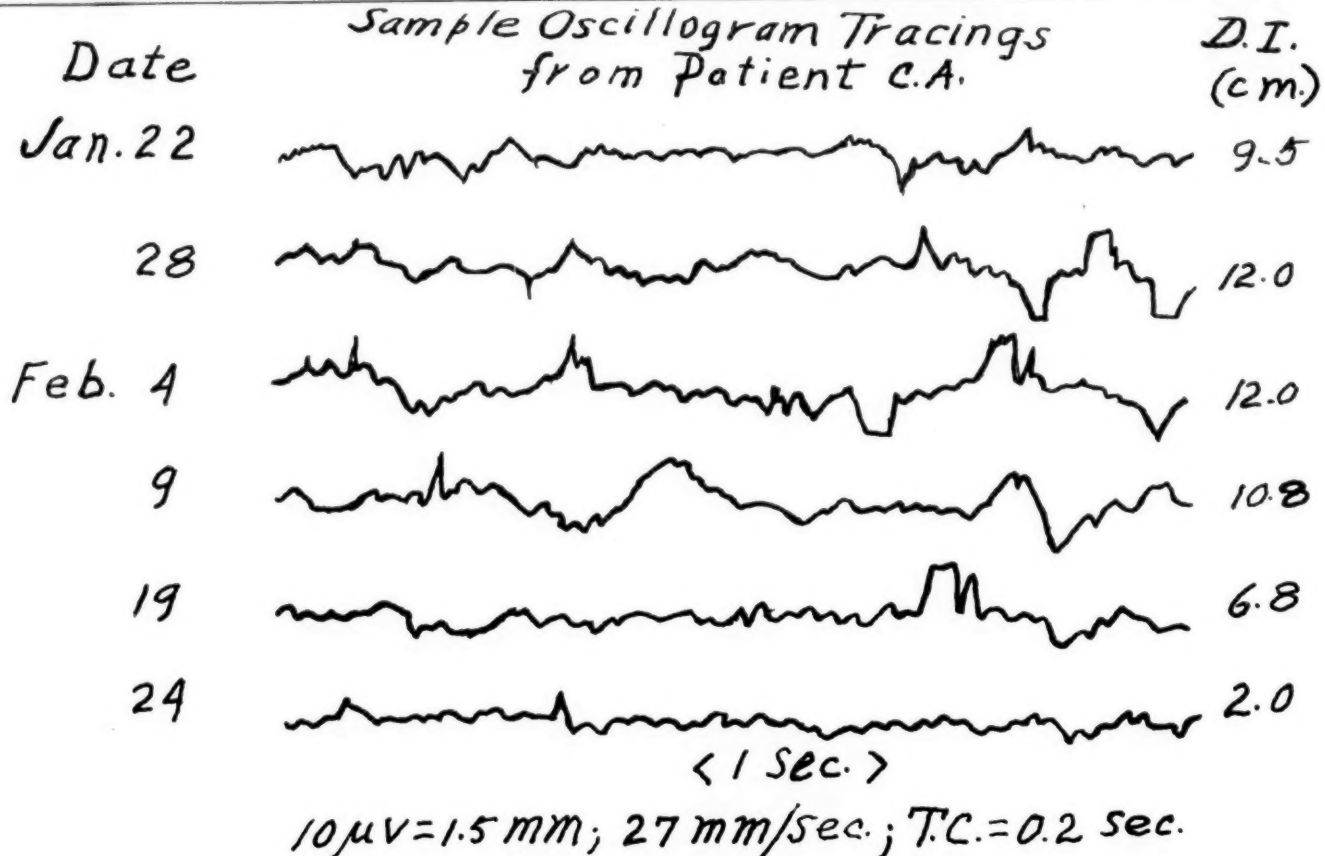

FIG. 1.—Sample oscillograms for the data of C. A. in Table 3 (see text).

Our most suggestive records in this regard were obtained from the patient J. M., not included in Table 4, which will now be given in some detail. This patient, who had been very ill for many months, was released from the hospital on October 19 in apparent full remission after evidently successful insulin therapy terminated on September 24, a date prior to the time we began recording brain waves. J. M. is an intelligent man who is helpful in discussing subjective aspects of his psychosis.

Our first record on October 14 yielded a D. I. of 0.3 cm. From time to time the patient returned to the hospital for examination. On December 1 we found his index to be 5.3 cm. but he reported himself as feeling well. Two days later fear that his thoughts might be read developed and he voluntarily returned to the hospital. His index then was 7.6 cm. He did not wish to remain for a new series of treatments but was, after some discussion, persuaded to do so. It is interesting that his index, after this decision and two hours after his return, had fallen to 4.0 cm. without a treatment, a decidedly significant drop, suggesting that the conversations and decision to remain and be treated may have had intrinsically some psychotherapeutic significance. His first treatment of the new series was given that same evening (December 8). The following table shows aspects of his case history in terms of his D. I.'s.

TABLE 4.

THE CASE OF J. M.

Second series of treatments daily, Dec. 8-21. The subsequent indices are "pre-insulin" D. I.'s. For discussion and case history of J. M., see text.

Date.	D. I. (cm.).	Date.	D. I. (cm.).	
Oct. 14.....	0.3	Dec. 12.....	1.5	
Dec. 1.....	5.3	14.....	0.8	
8.....	7.6	19.....	0.5	
2 hours later.....	4.0	23.....	0.6	(goes home for Christmas)
Dec. 9.....	0.8	31.....	1.9	returns once per week after this
10.....	0.1	Jan. 9.....	0.7	
11.....	0.1			

All symptoms, subjective or otherwise, were reported in abeyance from December 9 to January 18. On this latter date a time run, similar to those discussed in our first paper,[1] was made, the purpose being to study the hour-to-hour stability of his D. I. without treatment. Indices were obtained roughly every half hour during the day. Table 5 shows the results.

TABLE 5.

TIME RUN ON J. M. SHOWING TRANSIENT RELAPSE AT 10:17.

Time.	D. I. (cm.).	Time.	D. I. (cm.).
9:42	1.0	2:05	1.2
10:17	9.5	2:45	1.2
10:55	4.3	3:15	1.0
11:30	1.5	4:00	0.8
1:00	1.2		

The record at 10:17 was a great surprise to us. The patient had asked us about his record at 9:42 and we had told him of its integrated appearance. He also asked us about his second record and, in order not to alarm him, we evaded the question. After his third record he asked us again about the second record and we admitted it had appeared disintegrated. He then told us that prior to this record (D. I.=9.5), while waiting about the ward, he had intervened in a quarrel between two patients. Immediately afterward he said he had experienced a variety of compulsive ideas including one that he could never leave the hospital. It is interesting that his index had dropped to 4.3 at 10:55, about an hour after this transient relapse, the patient becoming more at ease and less tense. Fig. 2 shows typical oscillogram samples corresponding to the data of Table 5.

J. M. reported a good period when he returned for his next recording on February 1. However, his index at this time was 7.0 cm. We were careful not to tell him that his record looked disintegrated and he denied any subjective symptoms. Despite his high index we let him return home. The next day depressive symptoms with obsessive thinking to the effect that his thoughts could be read developed and lasted several days, but underwent spontaneous remission to a large extent before his next return for a recording on February 8. His index that morning looked rather

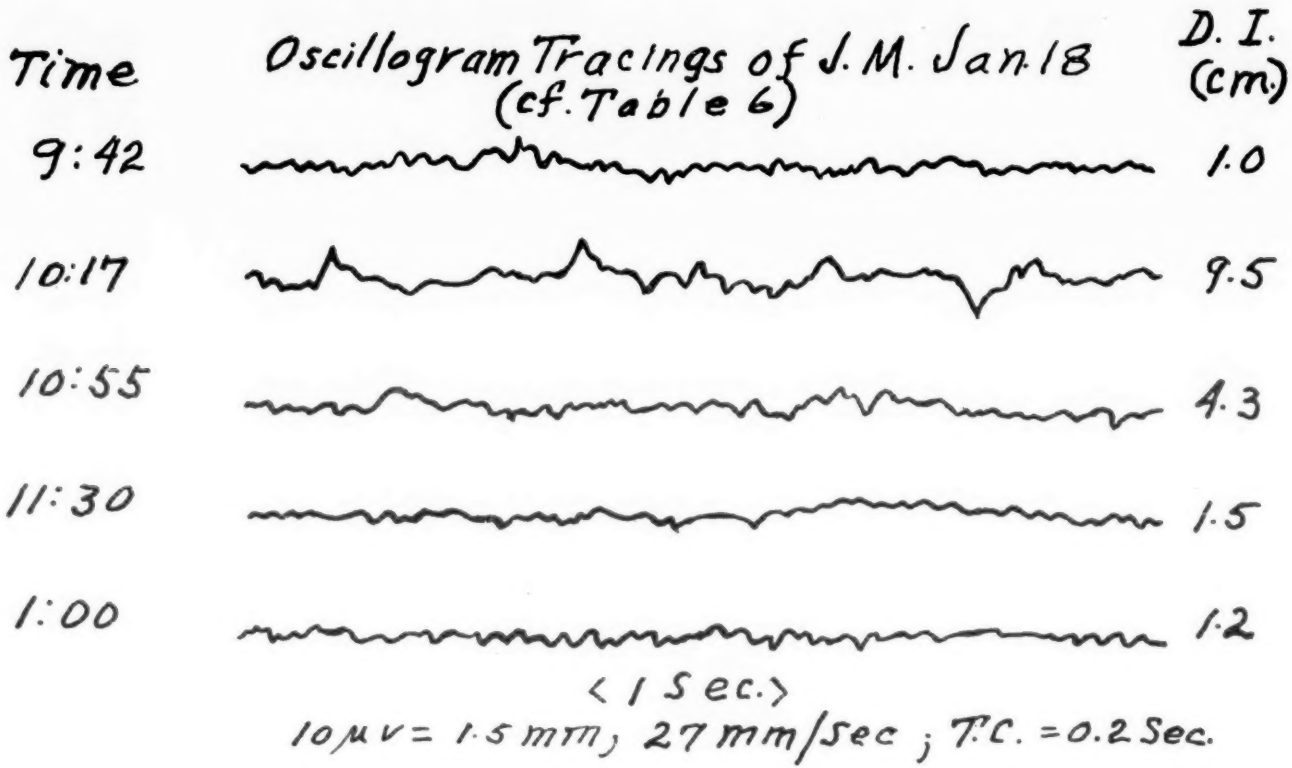

FIG. 2.—Sample oscillograms for J. M. showing increase in E. F. at 10:17 accompanying transient psychotic experiences.

high for him (it turned out on measurement to be 2.0 cm.) so we asked him to wait half an hour and have another recording. During this time he discussed with us (H. and R.) quite spontaneously his previous acute psychosis, we questioning him on certain of its subjective aspects. In the course of the conversation he asked us several questions concerning the biology of hermaphroditism and homosexuality. He seemed to have no personal interest in the subject but wanted information as a matter of curiosity. Neither of us knew at the time that during his acute early psychosis he had believed someone was trying to turn him into a woman.

At the time of our second recording on February 8 the patient seemed in every other way normal but his D. I. was 23.0 cm. So great was the change in the record that we removed and replaced the electrodes and recalibrated with extra care to make sure that the change was not a result of artefacts. After this recording J. M. said that on lying down his thinking became, as he termed it, "very mixed up." He said he did not think it had been brought on by the conversation since he often discussed his psychosis without being troubled, as he now clearly admitted himself to be. Nonetheless, it seems likely that some aspect of the conversation was inadvertently responsible, although he may still have been unstable (his earlier D. I. was 2.0 though normally <1.0) as a result of his spontaneous relapse earlier in the week. The patient wished to stay for more insulin treatments and was given one that evening. During the day the following indices were obtained prior to the treatment at roughly hourly intervals following his high factor of 23.0 cm.: 8.7, 8.1, 8.0, 10.0, 11.0, 10.4, 9.5 cm., and he reported continued compulsive depressive ideas. The next day after one treatment the value was 1.0 cm. and there was a remission of all subjective symptoms. A day or so later the patient went home, returning for a test on February 23. On this day his factor was 1.0 cm. and he reported himself as very well. In recent weeks J. M. has returned to the hospital once a week for an insulin treatment. Since February 23 we have only made one recording (March 1) and this yielded a pre-insulin index of 6.0 cm. Despite a subsequent treatment the patient says he experienced an acute depression with obsessive thinking 24 hours later on returning home.

FIG. 2.—Sample oschlograms for J. M. showing increase in E. P. at 16:17 accompanying transient psychotic experiences.

(*f*) *The D. I. as a Means of Control in Ambulant Cases.*—Recently we have initiated with patients J. M. and E. T., who have had prolonged hospital treatment but who have shown a tendency to relapse on returning home, a plan of ambulant insulin treatment. The patients are allowed to return to their homes and visit the hospital once a week or once every two weeks for a check-up and a treatment if necessary. In view of the fact that the observation of the relatives is naturally untrained, we have found that the delta index is of particular value. Should this ambulant method prove to be important, it seems probable that the D. I. may find considerably wider application. We feel that it has had especial value in the case of J. M.

Discussion.

On nine occasions we have noted changes in D. I.'s preceding corresponding *objective* changes in symptoms, *i. e.*, factors have increased preceding a relapse, decreased preceding a remission, or shown a plateau in advance of the clinical observations of a plateau in behavior. It is quite possible that changes in D. I. do not at any time precede subjective symptoms. We have been unable to answer this satisfactorily since most of our patients are noncommittal and uncooperative in describing subjective experiences, nor have we made any systematic efforts to tap their subjective lives in connection with D. I. measurements. Quite recently J. M. (whose "normal" D. I. is approximately 1.0 cm.) has admitted that on December 8, when we found his index to be 7.6 cm., that he was experiencing a strong subjective depression accompanied by compulsive ideas. These same disturbances were present but quite unsuspected by us at the time of his disintegrated records at 10:17, January 18 (D. I.=9.5) and again on February 8, second record (D. I.=23.0). On the other hand he assures us that he experienced no subjective symptoms on February 1 (D. I.=7.0) which preceded a relapse, on returning home, by 24 hours, nor on March 1 (D. I.=6 cm.) when the patient reported himself as well, but 24 hours later suffered a set-back after a treatment. Based purely on *objective* changes in symptoms, the index does, in an appreciable number of instances; four in Table 3, five with J. M., appear to precede the behavior change. In only two or three

instances have changes in indices occurred in a direction opposite to subsequent clinical developments (*cf.* Table 3). In these cases, however, subsequent indices were not taken until considerably later so that we are unable to say whether or not these changes may have presaged some temporary shift in the patients' conditions which escaped clinical notice. We feel that the fact that the D. I. has objectively indicated a relapse five times prior to behavior changes, including verbal admission, in the case of J. M., without ever misleading us by its fluctuations, is highly significant.

While clinical symptoms of mental patients are not quantitatively measurable, they nevertheless do fall on a rough qualitative scale so that we can designate the patient as worse, better, the same, etc., from one day to another. It occurred to one of us (H.) that the way of measuring the variability of the electrencephalogram outlined above might actually furnish an objective, quantitative description that would parallel the cruder clinical scale. The D. I. is indeed a measure of electrical variation in brain potentials as we have seen, the excess length in cm. being a function of the excess voltage produced by the brain over an arbitrary span of time for all waves longer than alpha waves. The content of the present paper indicates that the extension of this type of analysis to problems of psychiatry and neurology may prove of value.

A number of other problems related to the clinical application of the electrencephalogram to insulin treatment in schizophrenia have been considered. Among them was the question whether the D. I. would give any information of value in the selection of cases for insulin treatments. While it is too early to speak with certainty in this matter, it appears that the patients having a particularly high D. I. (15 to 20 cm.) do not respond as well as those having a D. I. within lower ranges. We have been particularly interested to ascertain whether the D. I. correlates with any particular aspect of mentation—inability to concentrate, tendency to projection, or formal disorders in the stream of thought, or whether the factors which produce the D. I. simply act as a substrate to behavior. While as yet we are not able to make a positive statement on this, it is to be recorded that there is no evidence of a correlation between the D. I. and the three aspects of behavior noted above. A useful lead may be furnished by the records on the patient J. C. in

whom the D. I. became about 1 cm. from a value of 3 or 4 cm. when the patient passed into a very deep stuporous phase. Clearly the state of being out of contact with the environment which occurs in stupor neurologically is different from that which occurs in sleep, since in the latter condition the D. I. rises markedly,[1, 2] while in stupor it falls.

We wish to reemphasize that we do not maintain that the D. I. by itself enables one to say whether or not a person is schizophrenic. Reasons for this are clear from Table 2. Both Berger[5] and Lemere[6] have described the electrencephalogram in schizophrenics and neither has reported a preponderance of long, slow waves. Jasper (personal communication) has assured us that he has not observed these waves in schizophrenics he has studied. There are several reasons why this is not surprising.

1. The waves are often qualitatively not conspicuous and, unless one is especially looking for them, they pass unnoticed. We would not have regarded the slow waves as significant had they not been so conspicuously modified by the insulin treatments. With rapid fluctuations in the psychosis, variations in the base line fluctuations from day to day were clear enough and called for a mode of measurement. Without a quantitative approach such as is furnished by the D. I., little can be said about comparisons of the occurrence of slow waves in normals and in patients since about half our schizophrenics give records with no more slow waves than we find in 90 per cent of our normal records. Only four out of thirty-one schizophrenics gave D. I.'s greater than 11 cm., the maximum for our normal group (*cf.* Table 2). The value of the D. I. so far has been in terms of its changes with a *given individual* patient.

2. It is possible that some selection of patients has been operative. This especially applies to our insulin patients since we have endeavored to select recently developed cases and avoid patients who are well reconciled to their institutional environment. We have observed that this latter class tend to have low D. I.'s. All of the patients recorded in Table 3 were selected because they started with high D. I.'s. Those with low initial D. I.'s are obviously unsuited to this type of analysis. Different institutions may also exert some selective action with respect to schizophrenic types.

3. Perhaps the main reason why our results may not be correlated immediately with the qualitative observations of others is because

of differences in amplifier characteristics used by different workers. In our earlier paper [1] we discussed in detail the effect of amplification, tape speed, line impedance, and time constant on D. I. All of these conditions play a highly significant rôle. We have used, for example, higher amplification than is usually regarded as convenient by most workers in studying the electrencephalogram in order to accentuate differences in D. I.'s. Unless our calibration conditions are precisely met by others, an unlikely state of affairs since our conditions have only just been published, we would not expect agreement. Moreover, unless measurements of D. I.'s under these conditions are *actually made,* it is futile to make comparisons since records giving, say, D. I.'s of approximately 8 cm. may fluctuate by ± 2 or 3 cm. and show no apparent difference in the predominance of long waves to the eye unpracticed in making these measurements.

To illustrate the importance of standardized conditions in D. I. determinations, it is worth mentioning that Dr. and Mrs. Hallowell Davis were at first unable to duplicate our results for reasons discussed in (1). They kindly brought their apparatus to Worcester and recorded *simultaneously* with us from the same patients. Three patients were selected for this study, one who gives a D. I. of about 2.0 cm., another of about 6.0 cm., and another of about 12.0 cm. After matching amplifiers and tape speeds, records were taken simultaneously by both recording systems from the *single* pair of electrodes attached to the patient.

Fig. 3 shows inked over oscillograms of typical synchronized records from the patients A, B, and C. The number 1 sample of each pair of records was taken with our apparatus, the number 2 with that of the Davises. Lines are drawn through each record to show the course of the map measurer in determining the D. I. The D. I.'s for both instruments on synchronized meter records agreed in most instances to within 1 cm. We do not wish to imply by this that the Davises have confirmed our findings relating D. I.'s and schizophrenia. Confirmatory experiments of this type have not been attempted. The comparison does, however, show that another amplifier can be matched to ours and that D. I.'s so determined are in agreement with those obtained with our apparatus.

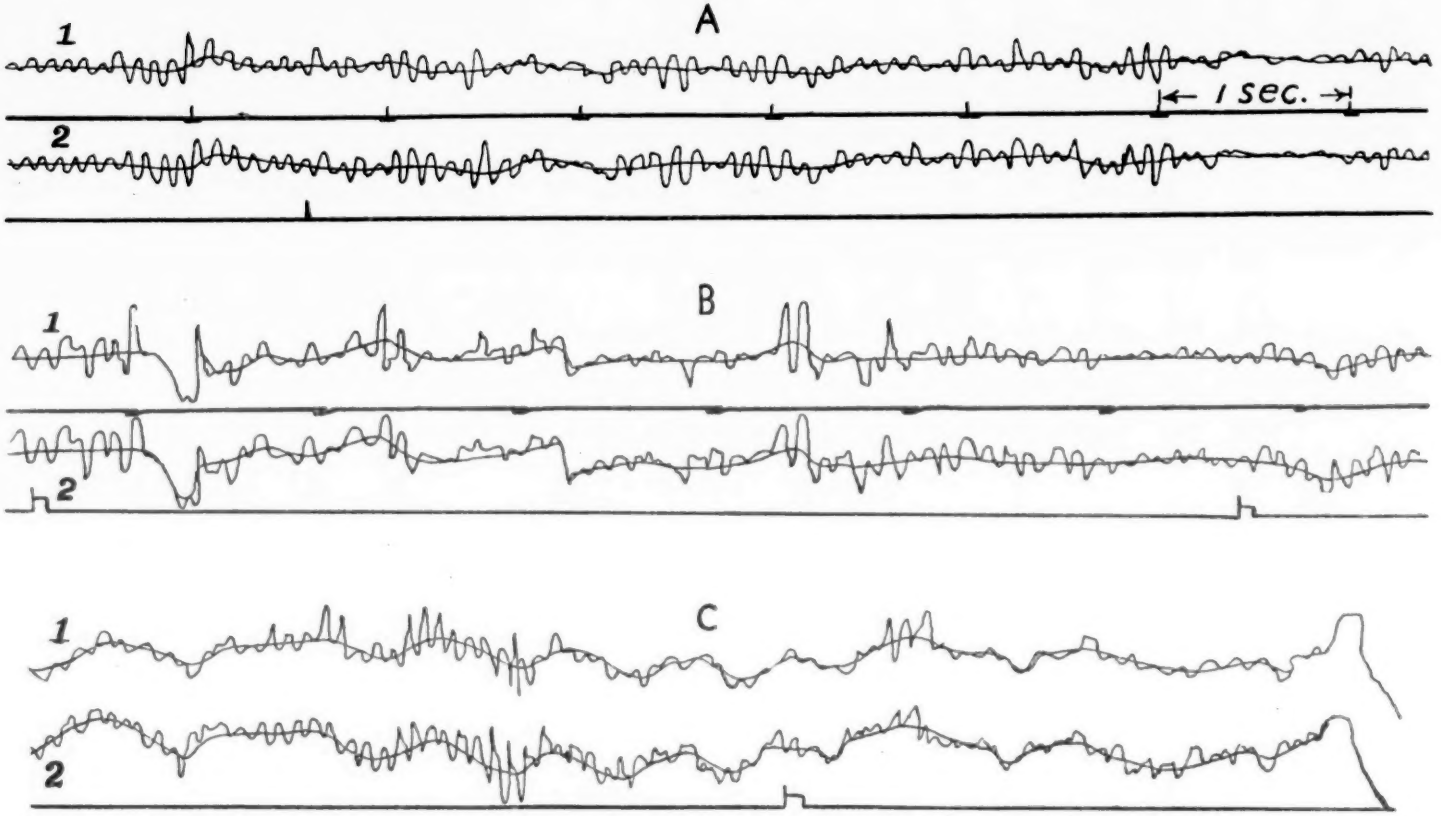

FIG. 3.—Sample oscillograms taken *simultaneously* with two entirely independent ink writers operated through different amplifiers after amplifier calibrations had been matched. *A*, *B*, and *C* are different patients; the numbers 1 and 2 refer to the different recording systems. Typical lines followed by the map measurer in determining the D. I.'s are drawn through the oscillograms.

Summary.

1. In 30 out of 35 insulin experiments the post-sugar delta index is considerably less than the pre-insulin delta index. In about this same proportion of cases patients show clinical improvement after treatments.

2. Mean delta indices for 37 normals are 2.1 cm., extremes 0.5-11.0 cm. Thirty-four of these were 3.2 cm. or less, the three higher values were 5.0, 6.0, and 11.0 cm. One normal awake gave a value of 0.5 cm.; asleep 10.9 cm. Twelve chronic alcoholics gave a mean of 2.5, extremes 0.5-6.0 cm. Nine manic depressives gave a mean at 2.8, extremes 1.0 to 5.2. Thirty-one untreated schizophrenics gave a mean of 6.6 cm., extremes 0.5 to 25.2. Twelve of these values were greater than the schizophrenic mean of 6.6 cm. Despite the mean differences the delta index cannot be regarded by itself as a measure of the schizophrenic state owing to overlaps in values between the groups of normals and patients.

3. Eighty-four delta indices taken on seven patients showing high pre-treatment indices, each over some weeks of treatment, exhibit in 88 per cent of the case complete correspondence with independently determined, fluctuating, objective clinical symptoms. With two other patients indices corresponded to symptoms in 60 per cent and 70 per cent of the instances. These two patients were verbally unresponsive and showed little detectable day-to-day change in symptoms to correlate with the indices. Patients who have "low" pre-treatment delta indices, *i. e.*, 4 cm. or less, about 50 per cent of a group of 31, cannot, of course, be analyzed by this method.

4. In schizophrenic patients we have found no special brain waves qualitatively different from those found in normal persons.

5. Transient relapses and remissions of one patient, earlier released after apparently successful insulin therapy, correlated completely with very specific fluctuations in his delta index.

6. In nine instances, with several patients, delta indices have been found to change prior to any other objective change in symptoms. Five of these nine prognostic changes were recorded with one individual.

FIG. 3.—Sample oscillograms taken *simultaneously* with two entirely independent ink writers operated through different amplifier calibrations had been matched. *A*, *B*, and *C* are different patients; the numbers 1 and 2 refer to the different recording systems. Typical lines followed by the map measurer in determining the D. I.'s are drawn through the oscillograms.

Comment.

WAR PROPHYLAXIS.

In an editorial comment in the JOURNAL for November, 1935, there was reproduced a formal statement drawn up by the Committee on War Prophylaxis constituted by the Netherlands Medical Association. This document, calculated to combat the dangers of the war psychosis and signed by psychiatrists from 30 nations, was transmitted to the statesmen of the world.

In a letter from the Netherlands Medical Association through D. J. Roveda its Honorary Secretary, dated at Haarlem in January 1937, progress in the campaign against war is reported, together with all the replies received from the statesmen of the various nations to whom the letter of 1935 was addressed, also press comments from 13 countries.

Upon the replies from the statesmen the committee comments: "We regret that those replies are not very important but we had not expected anything else." The replies vary from bald acknowledgment in two or three lines (example: "The Lord Chancellor acknowledges with thanks the receipt of the letter addressed to the Statesmen dated October 1935"), to elaborately polite agreement with the views expressed. From Washington comes the assurance that "The Department of State has been glad to give appropriate attention to the opinions expressed and appreciates your courtesy in transmitting this document."

There were exceptions however. From the Mongolian People's Republic came the following:

> We are in entire agreement with you that the reciprocal involvement of international interests and the influence of an international organization will enable the statesmen of the world to institute an effective campaign against war, and that peace will become much more secure than hitherto so soon as effort and money are devoted to the maintenance of peace commensurate with present outlay for armaments.
>
> We welcome therefore the initiative you have taken and declare our unqualified readiness to join in the movement toward a united front of all opponents of war—a movement which is certainly gaining impetus among the peoples of various lands. We are persuaded that a genuine collaboration

of peoples, even through the agency of presently existing international organizations, represents a potentially powerful factor in the peace of nations.

We harbor hatred for no people; we have no hatred for the Japanese people; and we firmly believe that the vast majority in every nation—even in Japan—is averse to war. It is necessary to make these majorities see clearly the danger of new wars and to organize their efforts for the maintenance of peace.

The words of the statement from which the foregoing paragraphs are extracted do not sound like the vacuous verbiage of customary diplomatic communications. This unique message is further noteworthy in the fact that it was signed by eight ministers of government and 171 leading intellectuals of the Mongolian Republic. For once it would seem that government and people are speaking the same language. Verily wisdom and good counsel came out of the East.

Official replies were received from 19 nations. France, Germany, Italy, Japan, Soviet Russia and Spain were not heard from.

The press of the world has taken encouraging note of the appeal of the Netherlands Medical Association, and for the most part echoed its challenge. The *Boston Evening Transcript*, under the caption "War Psychology, Analyzed, Becomes Form of Madness," says:

That whole peoples can be carried away, by the hypnotic power of propaganda until they are led into actions abhorrent under ordinary circumstances, is the chief warning contained in a remarkable document recently sent by the Committee on War Prophylaxis of the Netherlands Medical Association to the statesmen of the world. It was signed by 350 psychiatrists of 39 nations, and it presents for the first time a complete analysis of the whole field of war psychology.

But statesmen are only human beings, and heads of states are likely to partake least of those qualities which by a conspiracy of tradition and convention we agree to call "divine." All are subject to the same disorders of digestion, the same aging processes, the same circulatory disturbances as other men. The statesman, in the very nature of the case, seems bound to play a duplex rôle. His desire for power and domination must be discreetly clothed in the garment of public service. This makes it possible for him to protest that his personal critics are "enemies of the people." Rather more than in ordinary human affairs his acts are prone to follow upon motives which are unrecognized or at least unacknowledged, and which only succeed because they are hidden.

The *Boston Transcript* continues:

Statesmen are not always sane and responsible, mentally balanced individuals. They may be suffering from hidden fears, hates or unconscious urges to obtain power. Personal fears may be translated into public concern over the safety of the nation or real or imagined threats from neighbor nations. The personal urge for power, as a desire to spread culture to unenlightened groups and to carry the flag to the outermost reaches of the earth.

The *Baltimore Sun*, commenting upon the manifesto of the psychiatrists through the Netherlands Medical Association, says:

If the doctors seem innocently to have neglected fundamental aspects of the problem that agitates them—the economic roots of nationalism and war, and the political flowering of these roots—they have at least done a service, first in making plain that both the war and the preparation for war constitute, in a strict sense rather than mataphorical, a very real disease, and second, in recalling to the leaders that even in high places a pathological contradiction between pretensions and intentions can be seen for what it is.

From the *Berkeley Daily Gazette* we read:

Some great nations are today led by men known to be mentally unbalanced. This is the charge made by Dr. H. J. Norman, president of the psychiatry section, Royal Society of Medicine . . . . . Said Dr. Norman: "When we look about in the world we can still appreciate how applicable is the saying of the great Dr. Johnson when he pointed out 'As a madman is apt to think of himself as grown suddenly great, so he that grows suddenly great is apt to borrow a little from the madman.'"

There are at the present time individuals holding prominent positions and influencing the destinies of whole countries who are known to be mentally unstable or who have actually had attacks of mental disorder, declared Dr. Norman.

It is not unreasonable to hope that safeguards may somehow be set up so that such conditions will not recur in the future.

From the Province of Quebec we find in *Le Canada* the following paragraph:

Il semble que les psychiatres soient aussi impuissants que les politiques, lorsqu'il s'agit de définir des moyens pratiques de prévenir la guerre ou de la mettre, comme disent les Anglais, hors la loi. Leur intervention n'est pourtant pas inutile. On retiendra surtout le fait que les peuples n'ont pas la moindre idée de la chose épouvantable que serait une nouvelle guerre avec les engins de destruction que les puissances possèdent maintenant. Il faut les éclairer. C'est une œuvre à laquelle se devraient dévouer tous ceux qui sont en position de se faire entendre.

One of the most forthright declarations on the war psychosis and a vehement denunciation of war traffickers, pathological or

criminal, was uttered by the Karlsbad *Volkswille* under the caption: "Warning of the Psychiatrists." the *Volkswille* said:

Dass diese Welt vom Wahnsinn missregiert wird, dürfte für jeden Einsichtigen ausser allem Zweifel stehen. Neben den Unzurechnugsfähigen sind es die kalt spekulierenden Verbrecher, die das Elend dieser Erde auf dem Gewissen haben.

So ist es nur natürlich und konsequent, dass sich jetzt die Irrenärzte in aller Welt zusammengetan und einen Protest gegen das Chaos beschlossen haben, das diese Erde verwüstet. Die Irrenärzte sind gewiss competent, die pathologische Beschaffenheit unseres Zustandes zu analysieren, der übrigens fast unheilbar scheint. Aber die Psychiater haben noch einen anderen Grund, ihre gewichtige Stimme gegen den kommenden Weltkrieg zu erheben.

Sie wissen nur zu gut, was es mit der verlogenen Phrase vom reinigenden Stahlbad auf sich hat, sie wissen, welche Verwüstungen ein Krieg anrichtet, wie sich Geisteskrankheit und Verbrechen der Vernichtungsbahn der Tanks und Flammenwerfer anschliessen und wie sehr, neben der physischen Verwüstung, die seelische Dezimierung der Menschheit ihre grausige Orgien feiert.

Die Irrenärzte der Welt haben gesprochen. Mögen die Gesunden, die Mord, Vernichtung und Wahnsinn bedrohen, auf ihre warnende Stimme hören und den Geisteskranken die die Welt verpesten, ihr gemein gefährliches Handwerk legen, ehe es für all, für die Gesunden und für die Kranken, zu spät ist.

From Switzerland we read the following in the monthly psychological journal *Psyche*, published in Bern:

Es geschieht unseres Wissens zum ersten Male, dass jene Wissenschaft die wie keine andere dazu verpflichtet ist, asoziale und ahumane Kollektivwahngebilde zu zerstören und auf ihre primitive Wurzeln zurückzuführen, nähmlich die Psychiatrie, aus ihrem theoretischen Wissen als Seelenheilkunde auch die practisch-therapeutischen Konsequenzen zieht und eine wissenschaftlich begründete Auferklärung übernimmt, indem sie sich öffentlich und direkt an die Betroffenen wendet selbst wenn as Staatsmänner sind. Wir möchten wünschen, dass diese Art der angewandten Psychologie nicht ein einmaliges Ereignis sei.

Die Kundegebung der Psychiater ist wohl als Manifest wie auch als wissenschaftlicher Kundgebung von grösster Bedeutung. Wenn diese Botschaft der Seelenheilkunde an die Staatsmänner bei letzteren wirklich die Würdigung findet, die sie verdient, wäre von morgen an die seelische und wirtschaftliche Entlastung unmittelbar in der ganzen Welt zu verspüren. Das seelische Aufatmen, das durch ganz Europa gehen würde, wen dieser erstaundliche Einbruch der Wissenschaft in die Diplomatie therapeutische Wirkung hätte, würde bis in die Konsultationszimmer der Nervenärzte gehört—vielleicht besonders dort. Und so stellt sich kritischpsychologisch zum Schluss zwangsläufig nur noch die heikle Frage: was denn eigentlich von den Staatsmännern psychiatrisch zu halten sei, wenn diese klare Manifestation der Nervenärzte und Psychiater ohne therapeutische Wirkung verhalle?

The foregoing are samplings from the world press. Similar voices were raised in Latin America and in certain other European countries. As with the replies from the statesmen the response of the press was not universal. For the most part, however, this response contrasted with the sayings of the statesmen in its honesty of purpose and in the evident genuineness of desire, even though hardly hopeful, for international collaboration for the peace of the world.

The peoples of the nations desire peace. The intellectuals, the scientists, those with faith in the possibility of human progress and whose objective is the pursuit of culture desire peace. But the levels of mankind are determined by the hierarchy of the mind, and among leaders as among commoner men are inevitably those whose motivations are primitive motivations and who recognize no argument but that of force.

The voice of the psychiatrists of the world has at least been heard. In the broadcast of their unanimous declaration the Netherlands Medical Association has produced a historic document the influence of which may some day be more effective than in the present distraught state of world affairs. The Netherlands Medical Association has taken a forward step such as had not been done before. Encouraged by the results so far attained it is to be hoped that this distinguished body will continue energetically their campaign against the psychosis of war and of the makers of war.

PSYCHIATRY AT THE FIRST INTERNATIONAL CONFERENCE ON FEVER THERAPY.

(Condensed from a Report Prepared by Dr. Maurice Ducosté, of Villejuif, France.)

A meeting of unusual significance was the First International Conference on Fever Therapy, which was held in New York City, March 29-31, 1937.

Dr. Allen O. Whipple of Columbia University welcomed the congress, which included an organizing committee of scientists of 24 nations, delegates from the ministers of health of 16 nations, and Secretaries Drs. William Biernan and Andre Halphen.

French scientists gave the introductory reports on each question. In the opening speech Prof. Pierre Abrami of Paris discussed therapy fever in general, particularly from a biologic and therapeutic point of view. He first analyzed the two processes followed to provoke artificial fever; the intravenous injection of a foreign substance, usually protein; and the utilization of physical means, such as short waves or a warm, humidified atmosphere. In the first, "shock" is obtained: it escapes for the most part medical control; the reactions can be very brutal; it is not prudent to employ this method with exhausted or infected individuals; fatality is always a possibility to be considered, irrespective of the method. Fever, obtained by physical means, has none of the inconveniences; it brings no shock; the doctor can control it; he regulates at will its intensity and duration.

Since these two methods give similar therapeutic results, they must act by a common factor, probably not hyperthermia *per se*, as one might at first suppose. Certain shocks cure without elevation of temperature and already many physicians speak of pyretotherapy without fever. Thus, in malariatherapy some general paralytics have recovered without febril attacks, and Dr. Ducosté draws attention to frequent cases in which paludism inoculated into the cerebral substance of paralytics evolves without any rise in temperature, although the patients derive the usual therapeutic benefits from it.

In the second place, a patient may have a very high temperature for a long period without deriving any benefit from it, in typhoid and undulant fever, for example. If a shock-producing substance is injected into this patient, this shock may cure him in a few hours without the fever curve showing even a few tenths of a degree rise.

Finally, if hyperthermia were the sole agent, the two methods should give the same results. However, this is most often not the case: in acute gonococcic arthritis shock pyretherapy very frequently effects a cure in a single session, while pyretotherapy, by means of physical agents, does not cure these same lesions at equal temperatures except after many sessions.

Besides, if hyperthermia were the truly therapeutic element of pyretotherapy, shock pyretotherapy would have to be rejected in

favor of physical pyretotherapy, because of its uncertainties and frequent contra-indications as well as its actual dangers.

The author believes that what causes the cure of an illness, with one method or the other, is the sum of very complex biological reactions which are associated with artificially induced fever and especially the important modifications which take place in the functional state of the neurovegetative system. With protein therapy, these reactions are always much more violent and that is probably why this method often gives results which seem almost miraculous. On the other hand, the biological reactions (following injection of foreign protein) which are almost always associated with a febrile attack, can sometimes exist without hyperthermia and produce even in these cases the anticipated therapeutic results.

Prof. A. d'Arsonval referred to his work in 1882: "I am persuaded that the therapeutic of the future will employ as a curative means the physical modifiers, heat, light, electricity and other agents still unknown, and that the most poisonous drugs of chemistry will have to give place to these imponderables that have the advantage of introducing no poison into the organism."

Dr. Maurice Ducosté of Villejuif (France), delegated by the Prefect of the Seine, stated that artificial fever has cured many formerly condemned patients and saved the city of Paris much money, which has been used to improve Asylums of the Parisian region. Moreover, this success encourages hopes for a cure for dementia præcox in the near future.

Prof. A. Bessemans of Ghent (Belgium) considered the action of fever in experimental syphilis of the rabbit. The treponemes rapidly lose their mobility and virulence at a temperature of 40-42° C. A strict control of focal temperature is necessary, and can be obtained only with thermometers in quatrz, or glass thermometers filled with benzine or mineral oil.

Prof. Bessemans observed further a thermal adaptation of the treponeme comparable to that which he attributed to the pale treponeme *in vivo* of the lymph glands of the syphilized rabbit and to other functional varieties of the same parasite.

He concludes: the experimental and clinical results agree in suggesting for antisyphilitic thermotherapy repeated hyperpyretic treatments which combine physical methods and chemical spiro-

cheticides. Notably in the repetition of the treatment an important rôle is played by the mobilization of the lymphocytic forces in reserve.

Dr. L. Mary Moench of Cornell University presented a study of the heat sensitivity of the meningococci *in vitro* in therapeutic temperatures. The resistance of the cultures in medium semi-solid veal infusion agar is variable, but the fact that some are destroyed in 5 hours of heating or even less shows that the fever therapy could be advantageously employed in treating meningococci rebellious to serotherapy.

The reports of Prof. Ch. Richet, Jr., of Paris, "Posology of Therapeutic Fever," and of Profs. Leon Binet and Charles Gernez, also of Paris, "Physiology of Fever," aroused much discussion.

Dr. Charles Austin Doan of Columbus (Ohio) contributed a study of the differential reaction of bone marrow, connective tissue and lymph nodes to hyperpyrexia, which sheds light on the little-known action of fever in general paralysis.

Dr. James D. Hardy of New York City revealed his researches on the mechanism of heat loss in the human body, using Russell Sage's calorimeter. In natural fever, heat losses are due to radiation, convection and vaporization. It has been found that the mechanism for heat loss is adequate to care for twelve times the basal heat production. The spontaneous fever is due almost entirely to malfunction of the mechanism for heat loss, in fever produced by chills or without a chill.

Dr. Stafford L. Warren of Rochester, N. Y., insisted on the necessity of careful administration of chlorides and liquids in prolonged fevers, thus avoiding many of the sequellæ, such as nausea, vomiting, prostration, following hyperpyrexia.

Drs. Michael Pijoan, Israel Kopp and John Gibson of Boston (Mass.) spoke of the acid base balance during therapeutic fever. They conclude from their chemical analysis of the blood in the course of the fever that the therapeutic fever, characterized by severe dehydration and hyperventilation, brings about a pronounced alkalosis. The degree of alkalosis which approaches critical levels depends primarily upon the severity of the dehydrating and secondarily upon the extent of the hyperventilation.

They also report the changes which occur in blood chemistry; and Drs. Gibson, Kopp, and W. A. Evans, Jr., the changes in blood volumes during therapeutic fever. This last study was made on general paralytics, using the authors' blood volume method.

Comparative data are given on the per cent of reduction of plasma volume from pre-febrile levels occurring during fever induction by the use of typhoid vaccine, malarial organism, diathermy, the Kettering Hypertherm, and by means of radiant energy in cabinets with limited air space. No important change in volume occurs during fever induction by the two first mentioned methods. With diathermy, no considerable reduction in volume takes place until high temperatures have been reached. With the hypertherm, the reduction is extreme and occurs early in the course of fever induction with the result that a severe degree of tissue dehydration takes place by the time therapeutically desired temperatures have been obtained.

In the authors' opinion, the degree of dehydration and danger of serious circulatory disturbance is considerable during fever induced by the hypertherm, even when fluids are liberally given by mouth.

The preceding communications can be compared with those of Drs. Andrew Dowdy and Frank W. Hartman of Detroit (Michigan), on the preparation of patients for fever therapy with special reference to the administration of fluids and sedatives. They have found a carbamide sedative more satisfactory for the basic sedation than the barbituric acid group of drugs. Sedation is started the night before the treatment and completed the following morning approximately one hour before the fever therapy is started. The patient is given a high carbohydrate meal the evening prior to treatment, 500 cubic centimeters of 10 per cent glucose in physiological saline is given intravenously at 6.30 a. m. the morning of treatment. Breakfast consists of toast and tea at 7 a. m. During the pyretotherapy, the patient is given an iced solution consisting of six-tenths per cent saline, and 3 per cent glucose to take by mouth.

Dr. F. W. Hartman presented a study illustrated with microscopic photographs of pathological changes produced by artificial therapy in animals and man.

The exhibition of apparatuses included " Short Waves, a Perfect Pyretogenic Agent " by Dr. Andre Halphen and Dr. Jacques Auclair of Paris. They consider after treatment of 3000 patients for diverse diesase that short waves are the most powerful and easily controlled thermogenic agent. They praise the suppleness of the treatment, its simplicity, safety and comfort.

Prof. Clarence A. Neymann (Chicago) displayed a new machine for producing artificial fever.

Dr. Martha Brünner-Ornstein of Vienna discussed the development of physically produced fever therapy at the neuropsychiatric clinic in Vienna. She sees much promise in the combination of electrical pyrexia with chemotherapy.

Dr. W. Herr Russell of London employs two methods at the Temperance Hospital, London: a condenser field produced by ultra short waves (12 meters) and short wave electromagnetic induction (25 meters). He considers electropyrexia essentially a hospital treatment with specially trained doctors and nurses in constant attendance.

The sulphur fever therapy of Dr. Knud Schroeder of Copenhagen was presented by Dr. Tage Christiansen. He has used sulphurated oil (sulfosin) in combination with chemotherapy not only in the fever treatment of general paralysis of the insane and other syphilitic and non-syphilitic affections of the central nervous system, but also in schizophrenia and other forms of mental diseases, and in cases of chronic encephalitis. The many virtues of this method were elaborated and exact directions for its use were given.

Prof. G. Pamboukis of Athens observed during a dengue fever epidemic at Athens in 1908 that this fever and its toxins seem to have a special therapeutic effect. It is unfortunately impossible to control the illness on this side of the danger limits.

Prof. Antoine Alajouanine and Dr. G. Mauric of Paris reviewed the results obtained in France by pyretotherapy in neurology. The results are best in syphilitic diseases of the nervous system, while they are debatable in non-syphilitic affections, but further research is necessary.

A very large number of communications dealt with fever therapy in neurology, and various motion pictures were presented.

Prof. J. Wagner von Jauregg summarized his researches and stated:

> It was found that it makes no difference that the theoretical foundation of a therapeutic *method* is wrong, providing the therapeutic *success* is secured. We have learned that the spirochetes are present in the human organism for different periods of times and are still capable of living—even after a successful treatment. This holds true also for the gonococci. However, therapeutic results are obtained. Therapy is always empirical, therefore, we have to change the theory, and keep up the method of treatment.

Prof. Henry Claude and Dr. Pierre Rubenovitch of Paris had charge of "Fever Therapy in Psychiatry." They apply three methods: malaria inoculation, sulphur therapy and electropyrexia, with or without chemotherapy and opotherapy. They have employed these methods in general paralysis, manic-depressive psychoses and other psychopathies, confusional and schizophrenic syndromes. They believe that the effective factor in pyretotherapy from the theoretical point of view is the elevation of temperature and accompanying shock phenomena. In practice they prefer in the treatment of general paralysis the malaria inoculation followed by prolonged chemotherapy. However, they reinforce the effect of post-malarial chemotherapy by electric fever.

In confusional states, schizophrenia or dementia præcox, sulphur and colloidal gold therapy is applied to those in which a latent bacillary infection is suspected, while electropyrexia associated with opotherapy is applied to the others.

They insist upon the necessity for early treatment. This gave rise to a discussion, in which the value of pyretotherapy in the treatment of dementia præcox was seriously questioned, while insulin-therapy was esteemed to be perhaps of some potential value.

It was noted that fever exaggerated the individual's outstanding personality characteristics, and tended to induce delirious episodes in the unstable.

General paralysis, triumph of therapy, was the subject of many important communications. Drs. Leland E. Hinsie and Joseph R. Blalock of New York City analyzed the serologic results of a 12-year practice, numbering 326 general paralytics. Their results:

> 1. Ten years after treatment, 75 per cent of 28 patients had a negative blood Wassermann reaction; 89.3 per cent of 28 patients had a negative

spinal fluid Wassermann reaction; 100 per cent of 26 patients had a normal cell count in the spinal fluid; 75 per cent of 24 patients had a negative globulin reaction; and 73.1 per cent of 26 patients had negative gold sol curves.

2. Those patients who gained a clinical remission showed a higher percentage of negative serological reactions than the patients in other clinical categories. We do not believe that serological information may be unqualifiedly used in the prognosis of individual patients; it is valuable principally for comparing results in groups of patients. In our own experience, perhaps the safest time, if there is any, to estimate the future course of the patient's condition, from the standpoint of serology, is three or four years after treatment has been started.

3. With our group of 326 patients, the most favorable clinical and serological results were observed in those patients who received fevertherapy, followed by chemotherapy.

A number of other interesting papers could not be read, but will appear in the Reports.

The pyretotherapy of syphilis was studied by several authors. Drs. Walter M. Simpson and H. Worley Kendell of Dayton (Ohio) felt that although artificial fever shortens the treatment and increases its efficacy, vigorous, long-term inquiry in large clinics with suitably trained personnel is necessary before adequate treatment on a mass scale can be found.

Dr. Frank R. Menagh of Detroit, in his 3½ years experience in the treatment of syphilis by hyperpyrexia, obtained good results in general paresis and taboparesis (45 cases) and in tabes dorsalis (27 cases), but pain did not abate as much as he had hoped.

He concluded that artificial fever therapy is an important addition to the armamentarium of therapeutic agencies against syphilis, particularly in the more serious forms of the disease, which do not respond to chemotherapy alone.

There were no cases in this series where malarial fever produced satisfactory results when physically induced fever had failed. On the other hand, artificial fever showed a superiority only when a satisfactory degree of fever could not be obtained with malaria.

Dr. Clarence A. Neymann discussed the treatment of syphilis with artificial fever. Electropyrexia, according to careful statistics he presented, has increased the total rate of improvement 21 per cent and has virtually eliminated the 10-30 per cent death rate attributed to malarial therapy. A combined treatment with artificial

fever and arsenicals is highly recommended for general paresis, tabes and early syphilis. It is, however, too time-consuming and expensive for large-scale application.

Summing up, the First International Conference on Fever Therapy has brought to psychiatry very important general indications on the physiology of artificial fever, on the process and apparatuses that can provoke it, on the conducting of the treatments, and the therapeusis of the observable incidents. The results obtained from syphilographs were also shown to be important, and the advantages of fever therapy in general paralysis, tabes dorsalis and nervous diseases were demonstrated.

Most of the scientists urged the necessity of adjoining chemotherapy to artificial fever. Almost all agreed on the inutility of diverse pyretotherapic methods in the treatment of mental diseases, especially in dementia præcox.

K. M. B.

News and Notes.

MEETING OF THE AMERICAN PSYCHIATRIC ASSOCIATION.—The 93d annual meeting of The American Psychiatric Association was held at the William Penn Hotel, Pittsburgh, Pa., May 10 to 14, 1937.

On Monday, there were meetings of the sections on convulsive disorders and forensic psychiatry. The meetings of the section on convulsive disorders, including an informal evening round table dinner with 102 present, were joint sessions with the American Chapter of the International League Against Epilepsy.

The general session opened Tuesday morning, it being called to order by the president, Dr. C. Macfie Campbell. Following an invocation by the Reverend Bernard C. Clausen, there were addresses of welcome by Dr. Sidney A. Chalfant, president of the Allegheny County Medical Society and Dr. James K. Everhart, president of the Academy of Medicine of Pittsburgh, with a response by Dr. Ross McC. Chapman, president-elect.

The Association paid tribute to the memory of 33 deceased members, a special memorial to the late distinguished president, Dr. William A. White, being read by president-elect Chapman.

The presidential address read by Dr. Campbell evoked continued applause, the audience rising in appreciation. The address is printed in this number of the JOURNAL.

Three section meetings on Tuesday afternoon, included a symposium on child psychiatry; studies on habitation; and studies from the laboratory.

On Wednesday, there was a joint session with the section on psychoanalysis and The American Psychoanalytic Association; also sessions on brain pathology, clinical studies and therapy.

On Wednesday evening the annual dinner occurred at which there were 529 present. The address was given by John Gabbert Bowman, A. M., LL. D., L. H. D., Chancellor, University of Pittsburgh, on the subject "The Health We Need," his presentation being received with many favorable comments.

Following entertainment furnished by National Broadcasting Company artists, there was dancing with music by the Strollers Orchestra.

On Thursday, there were joint sessions with The American Psychopathological Association and the section on mental deficiency; also sessions devoted to hospital and extra-mural problems, clinical pathological studies, therapeutic procedures.

Thursday evening, 468 members and guests attended 12 round table dinner discussions, the subjects being child psychiatry, occupational therapy, psychiatric nursing, psychoanalysis, psychiatric private practice, psychosomatic relationship, scientific methods in psychiatry, The Veterans' Administration, tuberculosis in mental hospitals, forensic psychiatry, hypoglycemic treatment, and private psychiatric hospitals.

On Friday, there were three sections, including a symposium on hypoglycemia, mental deficiency and general topics.

Located near the meeting halls were scientific and technical exhibits. Various studies from the laboratory and from the field of clinical psychiatry were presented in the form of a scientific exhibit. Because of the practical character of the exhibits shown, the exhibit spaces were visited by a great number of members.

The following scientific exhibits were presented:

Untreated syphilis in the male negro and its relation to the involvement of the central nervous system. A comparative study of treated and untreated cases. The United States Public Health Service, Washington, D. C.

Trends in mental disease in New York State. Department of Mental Hygiene, State of New York, Albany, N. Y.

The psychoses with subacute (bacterial) and chronic verrucose (rheumatic) endocarditis. A clinico-anatomical study. Max A. Bahr, M. D., and Walter L. Bruetsch, M. D., Central State Hospital, Indianapolis, Ind.

Clinical electro-encephalography. W. G. Lennox, M. D., Department of Neurology, Harvard Medical School, Boston, Mass.; A. M. Grass, consulting electrical engineer, Harvard Medical School, Boston, Mass.; Hallowell Davis, M. D., and Pauline Davis, Department of Physiology, Harvard Medical School, Boston, Mass.

Comparative activities of mental hospitals. Mental Hospital Survey Committee, New York, N. Y.

In connection with the scientific exhibit, organized by Dr. Bruetsch, a number of films were also shown at intervals depicting hospital activities.

The commercial exhibits included displays of importance and particular interest to mental hospital administrators.

The Ladies Reception Committee and the Arrangements Committee formulated a program of interesting luncheons, shopping tours, sight seeing trips and other attractive affairs which increased the pleasure of the ladies.

In accordance with the report of the Board of Examiners and upon recommendation of the Council the Association elected 31 to associate membership; 159 to membership; 12 transferred from associate membership to membership; and 11 transferred from membership to fellowship.

The following were elected officers for 1937-1938:

Ross McC. Chapman, M. D., President, Towson, Md.
Richard H. Hutchings, M. D., President-Elect, Utica, N. Y.
William C. Sandy, M. D., Secretary-Treasurer, Harrisburg, Pa.
Council members elected for three years: Charles H. Dolloff, M. D., Concord, N. H.; George S. Johnson, M. D., San Francisco, Calif.; Harry C. Solomon, M. D., Boston, Mass.
Robert P. Winterode, M. D., Crownsville, Md., was elected an auditor for three years.

The following were elected the officers of the sections for 1937-1938:

Section on Convulsive Disorders: S. Bernard Wortis, M. D., Chairman, New York, N. Y., and William G. Lennox, M. D., Secretary, Boston, Mass.
Section on Forensic Psychiatry: Winfred Overholser, M. D., Chairman, New York, N. Y., and James L. McCartney, M. D., Secretary, Catskill, N. Y.
Section on Mental Deficiency: Ransom A. Greene, M. D., Chairman, Waverly, Mass., and Oscar J. Raeder, M. D., Secretary, Boston, Mass.
Section on Psychoanalysis: Nolan D. C. Lewis, M. D., Chairman, New York, N. Y., and Clarence P. Oberndorf, M. D., Secretary, New York, N. Y.

San Francisco, California, was selected for the 94th annual meeting in 1938, the place for headquarters and the exact time to be decided later by the Executive Committee and the local Committee on Arrangements.

The total registration was 1358, of which 500 were members. Forty-two states, Canada and Australia were represented. Since the meeting, many complimentary expressions have been received as to the very satisfactory program and general arrangements.

WILLIAM C. SANDY, M. D., *Secretary.*

CALENDAR OF PSYCHIATRIC MEETINGS.—The American Psychiatric Association is collaborating with The National Committee for Mental Hygiene to keep on file a calendar of psychiatric meetings in all parts of the country. The office of either organization will be gratified to receive dates and programs, and will have this information available for inquiries. It is hoped in this way to avoid conflict between important psychiatric events. For instance, the Salmon Lectures are an outstanding event of the psychiatric year, and it is hoped that other organizations may be able to set the dates of their meetings in such a way as to allow their members to attend these lectures in as many instances as possible.

THE AMERICAN COLLEGE OF PHYSICIANS 1938 MEETING.—The twenty-second annual session of the American College of Physicians will be held in New York City, with headquarters at the Waldorf-Astoria Hotel, April 4-8, 1938.

Dr. James H. Means, of Boston, is President of the College, and will have charge of the program of general scientific sessions. Dr. James Alex. Miller, of New York City, has been appointed General Chairman of the Session, and will be in charge of the program of clinics and demonstrations in the hospitals and medical schools and of the program of Round Table Discussions to be conducted at headquarters.

RESIDENCES IN NEUROPSYCHIATRY.—Four residences per year have been approved by the Council on Medical Education and Hospitals of the American Medical Association for the Menninger Sanitarium, Topeka, Kansas. Residency periods now begin January 1, April 1, July 1, and October 1. The candidate for the January 1, 1938 appointment will be chosen October 1; all applications must have been received by September 1 so that the credentials and references can be investigated prior to the appointment of the resident. Minimum requirements for candidacy are graduation from an approved medical school and the completion of an interneship in an approved hospital. The salary for residents is $120 a month without maintenance.

Didactic instruction is arranged with the staff members, and the residents are eligible to attend seminar discussion groups, staff con-

ferences, the sessions of the post graduate courses for nurses and for physicians, and class work in neurology, neuropathology, psychiatry, and psychoanalysis.

Application blanks will be mailed upon request. Address Dr. Karl A. Menninger, Chief-of-Staff, The Menninger Clinic, Topeka, Kansas.

Bureau of Human Heredity, London.—Attention is drawn to the very important service provided by this Bureau, a service to which all those interested in human genetics may contribute, and from which they may likewise derive benefit.

The object of this Bureau is collection on as wide a scale as possible of material dealing with human genetics. Later, the tasks of analysis of material and distribution of the information available will be added.

The Bureau is directed by a Council representing medical and scientific bodies in Great Britain. It is affiliated to the International Human Heredity Committee, which ensures cooperation in all areas where research is proceeding.

The Council would be grateful to receive all available material from Institutions and individuals, furnishing well-authenticated data on the transmission of human traits whatever these may be. Pedigrees are particularly desired; twin studies and statistical researches are also relevant. As research workers and others who send in material may in some cases wish to retain the sole right of publication (or copyright) those who so desire are asked to accompany their material with a statement to that effect.

Material should be given with all available details in regard to source, diagnostic symptoms and the name and address of the person or persons who vouch for accuracy. All such details will be regarded as strictly confidential.

Reprints of published work would be most acceptable. Further, many authors when publishing material may also have collected a number of pedigrees which they have been unable to reproduce in detail. It is the object of the Council that such records, by being included in the Clearing House, should not be lost.

Those wishing for a copy of the Standard International Pedigree Symbols may obtain one from the office.

Announcements in regard to the services undertaken by the Bureau will be published from time to time.

Chairman: Prof. R. Ruggles Gates, F. R. S., 115 Gower St., London W. C. 1, Eng.

Executive Committee: R. A. Fisher, J. B. S. Haldane, E. A. Cockayne, J. A. Fraser Roberts, L. E. Halsey (Hon. Treasurer), C. B. S. Hodson (Hon. Gen. Secretary).

AMERICAN ASSOCIATION ON MENTAL DEFICIENCY, ANNUAL MEETING.—The sixty-first annual meeting of the American Association on Mental Deficiency was held at Haddon Hall, Atlantic City, N. J., May 5-8, 1937. There were thirty-five papers presented which will be published in the Proceedings.

Dr. Harry C. Storrs of Wassaic, N. Y., was elected President. Dr. Neil A. Dayton of Boston, Mass., was elected Vice-President and Dr. E. Arthur Whitney was elected Secretary-Treasurer. These officers to serve for the year 1937-38. Councillors elected for four years were Dr. B. O. Whitten of Clinton, S. C., and Dr. Warren G. Murray of Dixon, Ill. Miss Mabel Matthews of Mansfield Depot, Conn., was elected auditor for three years.

The place of meeting for 1938 will be in Richmond, Va., April 20-23.

The Association has surmounted its financial difficulties and is "out of the red." One hundred and fifty new members were elected to membership at the final business meeting on May 8.

There were many outstanding contributions to the program including papers by the following: Dr. Adrien Blyer of St. Louis, Mo.; Dr. C. A. Mills of Cincinnati, Ohio; Professor Ellsworth Huntington, of New Haven, Conn.; The Hon. Franklin Kirkbride of New York City and Dr. F. V. Willhite of Redfield, S. D.

An interesting innovation of the convention was the bringing of the activities of the various institutions to the convention in place of the usual visits to institutions by those attending the convention. Exhibits of institutional activities were shown by The Training School at Vineland, N. J.; The Elwyn Training School, Elwyn, Pa.; New Lisbon Colony, New Lisbon, N. J.; The Vineland State School, Vineland, N. J.; The Woodbine Colony, Woodbine, N. J.;

The North Jersey Training School, Totowa, N. J., and The Dept. of Institutions and Agencies of the State of New Jersey.

Some 300 members attended the convention.

MEETING OF THE ACADEMY OF PHYSICAL MEDICINE.—The fifteenth annual meeting of the Academy of Physical Medicine will be held at the Hotel Walton, Philadelphia, October 19, 20, 21, 1937.

The Academy, which is international in scope will present a scientific program based on reports of the most recent research and practice of the various specialties. In addition to the lectures, demonstration clinics will be held at the hospitals of the University of Pennsylvania, Jefferson Medical College, and Temple University.

A copy of the program may be had by addressing:

William D. McFee, M. D., Chairman,
Committee on Program and Publication,
41 Bay State Road, Boston, Mass.

Book Reviews.

ADMINISTRATIVE PSYCHIATRY. By *William A. Bryan, M.D.* (New York: W. W. Norton & Co., 1936.)

Books, and even articles in the periodical literature, dealing with the practical problems of operating mental hospitals have been scarce. It is therefore of particular interest to record the appearance of a book on this topic written from a practical viewpoint by a superintendent of long experience and progressive attitude. Doctor Bryan, for over 15 years superintendent of the Worcester (Mass.) State Hospital, has compiled a volume which should be of interest and value to all psychiatrists engaged in institutional practice. Although a book on hospital administration it does not devote itself to the operation of the farm, or the power-plant, or the storehouse; rather it deals with the various aspects of the care of the individual patient, and to the manner in which the hospital may best fulfill its function as a community agency.

After outlining the several methods of state organization, such as boards of control, boards of trustees, departments of welfare and departments of mental hygiene (the New York law is incorrectly stated), the author discusses types of hospital organization, distinguishing the one-man type, the dual-headed type, and (his own preference and practice) what he denominates as the "participative democracy." Doctor Bryan gives the five functions of the mental hospital as: (1) the practice of psychiatry; (2) medicine and surgery; (3) teaching; (4) research; (5) prevention. Chapters are devoted to each of these topics, as well as to such subjects as the nursing problem, group psychotherapy, occupational and industrial therapy, the contribution of social work and public relationships.

One cannot well summarize the chapters; they contain many stimulating suggestions, and should be read *in extenso*. A few points only are mentioned. The author advocates the development of "standard practice" manuals, which will give detailed information as to routine hospital procedures. This manual would be placed in the hands of the staff physicians and of the several department heads; it would be a loose-leaf affair, and subject to continuing revision by a committee of staff members. The advantages of this procedure over the all-too-frequent passing on of tradition by word of mouth are obvious.

A separate medical and surgical service is advised, distinct from the psychiatric service, though definitely an adjunct of the latter. In this service the aid of an active consulting staff should be systematically utilized. Such services, when established, have functioned satisfactorily.

Much stress is laid upon the importance of rapport with the patient, and of establishing in him confidence in the hospital and physicians. Very gratifying results are reported from the use of an orienting letter which is de-

livered to the patient upon admission; radio talks to patients about the work and aims of the hospital, and on mental hygiene, have proved themselves valuable. Still another group-therapeutic procedure is the grading of patients (p. 182). The author is an enthusiastic advocate of family care as an aid in the readjustment of the patient to community life.

The important question of the public attitude toward the hospital, and the means of influencing and improving that attitude, are frankly and constructively discussed, with a number of helpful suggestions.

Whether or not one agrees with all the conclusions and suggestions, the book is practical and forward-looking and should be read by all engaged in mental hospital work. It would be helpful, too, if our newspaper editors and our politicians likewise read it; such perusal would be a step toward establishing a more intelligent public opinion concerning the significant contribution of the mental hospital to the welfare of the community.

WINFRED OVERHOLSER.

TWINS: A STUDY OF HEREDITY AND ENVIRONMENT. By *H. H. Newman, Frank N. Freeman, and Karl J. Holzinger.* (Chicago: University of Chicago Press, 1937.)

The material on which this study is based consists of the following: (1) 50 pairs of monozygotic twins, reared together; (2) 50 pairs of dizygotic twins, reared together, used as a control group; and (3) 19 pairs of monozygotic twins, reared apart. The twin-pairs have been investigated for physical and mental resemblances and differences: stature, weight, head measurements, finger prints, handedness, etc.; intelligence tests, educational achievement tests, temperament tests, etc.

The findings yielded by Stanford-Binet tests are of great psychiatric interest. Among the 50 pairs of monozygotic twins reared together, the I. Q.'s were identical or differed by not more than 5 points in 24 cases; in the remaining 26 cases there were differences up to 20 points. In the group of 50 pairs of dizygotic twins, the I. Q.'s were identical or differed by not more than 5 points in 17 cases; in the remaining 33 cases there were differences up to 40 points.

The contrast between the monozygotic and dizygotic groups is accounted for, of course, by the fact of the identical heredity of the monozygotic twin-pairs. The authors are inclined to attribute the more or less marked differences found in 26 of the monozygotic twin-pairs to prenatal factors, such as inequalities of fetal blood supply and an "asymmetry mechanism" in development. In support of the latter factor the abnormal frequency of left-handedness in one of a pair of monozygotic twins is brought forward. The facts as regards handedness are, however, confusing. It is true that in 24.1 per cent of cases of monozygotic twins one is left-handed, the other right-handed; but among dizygotic twins, too, the same thing is found in 15 per cent of the cases. The authors state, "This is a real mystery which has not yet been cleared up." Moreover, in 3.7 per cent of the cases of monozygotic twins, *both* of each pair are left-handed. In view of the rather overwhelming evi-

dence that is available in other material it seems strange that the authors have failed to take cognizance of the factor of birth injury involving the left cerebral hemisphere as possibly accounting for differences in both intelligence and handedness in monozygotic twin-pairs and for the abnormal frequency of left-handedness among both monozygotic and dizygotic twins.

Among the 19 cases of monozygotic twins reared apart the I. Q.'s were identical or differed by not more than 5 points in 8 instances: 42.1 per cent, as compared with 48.0 in the monozygotic twins reared together. In the remaining 11 pairs there were differences in I. Q. up to 24 points. In other words, in the results of the Stanford-Binet intelligence tests there seems to be no significant difference between the group of monozygotic twins reared together and those reared apart.

A. J. R.

PRACTICAL EXAMINATION OF PERSONALITY AND BEHAVIOR DISORDERS. By *Kenneth E. Appel and Edward A. Strecker.* (New York: The Macmillan Co., 1936.)

The authors of this book state that its purpose is to guide the student in the technique of psychiatric observation, that it is designed to be used in the same way as a laboratory manual, and that it is compiled from the methods they have followed in their teaching.

The book is divided into two parts of exactly one hundred pages each, by a chapter, in the form of a questionnaire, on the emotional health of the medical student. The first part covers the psychiatric examination of adults, the second that of children.

Besides outlining the formal information necessary to be obtained on any case, actual questions which can be asked are included and valuable hints as to how and when to ask the questions are added, so that the student who makes intelligent use of the manual should be greatly aided not only in making his examination but in understanding his case. The chapter on the "Art of Psychiatric Examination" is the meat of the book and the italicized portions, such as, "hastiness and pressure of work prejudices a good examination" and "take the history personally from both family and patient," are well chosen.

The portion of the book concerning children consists of the formal outline with appropriate questions followed by chapters on Parent Child Relationships and Child Guidance Problems.

A comprehensive useful book which can be recommended.

PSYCHOLOGICAL STUDIES OF HUMAN VARIABILITY. Psychological Monographs. Dodge Commemorative Number. Edited by *Walter R. Miles.* (Princeton: Psychological Review Company, 1936.)

This number of the Monographs (Volume XLVII, No. 2) is presented to Professor Raymond Dodge, on the occasion of his voluntary retirement from

active academic work, as a tribute to 40 years of distinguished service to psychology. It represents an enterprise participated in by former students and colleagues of Professor Dodge, which, to quote the editor, "combines science with friendship." Five introductory articles deal with appreciative, bibliographic, and descriptive statements concerning the contribution to which the entire volume pays tribute; and 29 experimental, historical and theoretical articles follow. These latter all deal with problems rooted in the fundamental work of Professor Dodge, and indicate in a very real way his inspiration to American psychology, the remarkable scope of his work, and the scientific spirit of his investigations.

PROSTITUTION: AN INVESTIGATION OF ITS CAUSES, ESPECIALLY WITH REGARD TO HEREDITARY FACTORS. By *Tage Kemp*. English Translation by *Elsie-Marie Werner Kornerup, B. A.* (Copenhagen: Levin & Munksgaard, Ejnar Munksgaard, 1936.)

This book deals with prostitution and its causes, with special reference to hereditary factors. It is the result of a series of investigations made in Copenhagen between 1931 and 1935, during which time 530 prostitutes were given a medico-psychiatric examination, with special attention paid to inherited traits. The book contains 50 case records in full.

The author approaches his subject from a purely objective standpoint, regarding prostitution as a biological phenomenon without harboring moral or political prejudices. He points out, however, that it is impracticable to avoid entering into the social conditions and legal interpretations which form an ever-present background for this problem. The investigation was begun at the request of Police Superintendent Schepelern-Larsen, who for 30 years has been chief of the Health and Morality Police in Copenhagen. The psychiatric work was done under the general direction of Professor August Wimmer, director of the Psychiatric Clinic of the University of Copenhagen, assisted by Doctor G. E. Schroder and Doctor Max Schmidt. Assistance was rendered in the genetical problems by Professor Oluf Thomsen, the director of the University Institute of General Pathology in Copenhagen.

The book deals with a brief historical account of prostitution; details of the method and extent of investigation; the causal significance of hereditary factors in prostitution; and the relationship of environmental influences in childhood and adolescence. The mental qualities and abnormalities of prostitutes is discussed with reference to bodily illness and with special reference to venereal disease. Conditions affecting adult situations such as poverty, unsatisfactory working conditions, family and social problems are briefly reviewed. The application of correctional procedures and measures is also touched upon.

The last chapter of the book is devoted to a summary and conclusion, followed by a fairly complete bibliography.

The author points out that only 29.4 per cent of the cases examined were mentally normal or without defective intelligence. Of those examined 22.5 per cent were pronounced psychopaths; 0.8 per cent were imbeciles; 6.8 per cent were morons; 19.1 per cent were regarded as dullards; and 23.2 per cent were below the average or retarded, whereas 36 per cent had committed actual criminal offenses.

The study indicates that the majority of prostitutes are below normal mentally, but this abnormality was insufficient for a court to declare such individuals incapable of managing their affairs. It was thought from the study that they belong to a "borderline" group of psychopathic characters and that many of the same type were found among the collaterals of their family. All seemed to lack the ability to properly adjust themselves socially or they were actually anti-social in their adaptations.

The case records cited illustrate the way in which society deals with these borderline groups, often highly unsuited for the purpose, and that legislation and administration of the subject has frequently proven unsatisfactory. The author comments that "if we reflect to where and how widely eugenic sterilization could have been advantageously undertaken in these families, we come to the conclusion that the possibility of carrying out rational, effectual sterilization on a firm scientific basis, on a certain social group such as is represented here is in reality slight."

The ways and means suggested by the author to improve the existing conditions would include an educational program for parents, guardians, school authorities, homes, reformatories, police authorities and courts with reference to psychopathic abnormalities of the borderline type; with the necessity for obtaining psychiatric assistance and guidance for the disposition and treatment of such persons; and with such regulations as may be necessary for the extensive use of psychiatric examinations in connection with the legal disposition of prostitutes.

The author also calls attention to the necessity for permanent community supervision of the "slightly mentally defective person" not requiring institutional care by such agencies as boards of guardians that may exercise supervision over adolescents and the general supervision of persons discharged from homes, reformatories, mental hospitals, and those released from prisons and workhouses.

The recommendation again appears to the effect that efforts should be made to detect the difficult and mentally defective children already in school, and to arrange for the special training of those who cannot profit by the usual course of study, keeping such persons under constant guidance during the compulsory education period. The book recommends, for mentally abnormal prostitutes who are not defective enough to be placed in mental hospitals or institutions for the feebleminded, that they not be subjected to police control, fines and imprisonment, but be placed under some type of provident care and control, or perhaps in an institution especially suited to their needs. The need for "morality police," cooperating with public welfare institutions more extensively than has been the custom, is recommended,

and that the practice of imprisoning and fining prostitutes such as is now the case is neither suitable nor necessary for the solution of the problem. The author recommends the general reduction of social inequality and especially the improvement of working conditions for female domestic servants.

W. L. T.

HINTS TO PROBATIONERS IN MENTAL HOSPITALS. Third edition. By *Richard Eager, O. B. E., M. D.* (London: H. K. Lewis and Co., Ltd., 1936.)

This book is, as implied in the title, chiefly a list of little rules of procedure for nurses in mental hospitals. In its original form this was apparently all it was intended to be; this edition, however, states that its purpose is to be generally useful to mental nurses. It cannot be said that this purpose is entirely fulfilled.

The book opens with these words, "It is generally accepted to-day that the brain is the organ of mind, and that it is the delicate structure of the brain that is deranged in patients suffering from mental disorder, no matter how minute this may be." This seems to be somewhat contradicted on page 78. "I have already explained that 'mind' is not material. Abnormalities cannot be seen on the post-mortem table. . . . ." Without attempting to discuss the theories in question, it does seem that their presentation would not be entirely clear to nurses-in-training.

Part I includes the actual "Hints to Probationers." These consist of a series of rules "which have stood the test of time," *e. g.*—"Never tackle an excited or violent patient single-handed"; "Never leave the door of your room unlocked." In this section also are a chapter on ward duties, a chapter on psychology, and one on dreams.

Part II is a slight description of "the various forms of mental disorder with the nursing duties in connection with each." This list of mental disorders includes no mention of the milder or borderline disabilities, or of the maladjustments of children; and the book contains no single reference to any possibility of prevention, and therefore, of course, nothing on the nursing aspects of these matters. There is no attempt to describe the whole programme of attack on mental disease, and no information as to the available facilities for treating it. As for nursing itself, as here presented it would appear to consist not only in part but entirely of the most elementary routine ward duties.

Reliable sources of knowledge of psychiatric nursing are so few that one should welcome an attempt by an authority to deal with the subject. One feels however, that the content of this branch of nursing is still largely to be discovered and organized; and that a rather fuller presentation, for nurses, of psychiatry itself would be a better basis on which to build a nursing text.

PRISONS AND BEYOND. By *Sanford Bates.* (New York: The Macmillan Company, 1936.)

Although written from the standpoint of the prison executive, "Prisons and Beyond" is a book that not only indicates problems in prison management but has particular interest for the psychiatrist in that it points the way toward a more scientific, effective and humane treatment program for those convicted of crime.

Imprisonment, as we use it today, is of comparatively recent origin and certainly the particular problems it raises developed simultaneously with our industrial expansion. Imprisonment was by no means the first method of dealing with culprits and although it is now practically the only one employed, Sanford Bates indicates that other forms of management might well supplant the current fad.

With the thesis that the end and aim of a penal system is the protection of society and not individual or social vengeance, the problem immediately raised is how society can best be protected against the criminal. Certainly not by maltreating him in an institution for a year or more. If our present statistics on recidivism are discouraging the deficiencies in our present methods of treating prisoners may well be the reason. As this very interesting book is read one loses any respect he might have had for the various theories of penology except those directed toward a constructed rehabilitation of the individual and which are intended to help him resume a place in society. Certainly these worthwhile theories are emasculated by our present practice of attempting to salve the wounded feelings of society by the imposition of some definite period of time which must be served before the offender can be considered eligible for treatment.

Mr. Bates emphasizes that the modern institution must make full use of the knowledge which the psychiatrist, the psychologist, and the sociologist may contribute toward the solution of its problems. "The psychiatrist," he says, "or character analyst, or therapist, or whatever he may be called is in prison work to stay. No approach can be made to the solution of the problem of individual rehabilitation without his insight and assistance." But here he adds a word of admonition, not to say—a warning: "He (the psychiatrist) must now content himself, however, with diagnosis. He has been too prone in the past to tell us what was wrong with our offenders without going into the necessary details of what should be done to correct and cure these defects." This is a point which is well taken but it is not entirely the psychiatrist's fault; even Mr. Bates has not been able to suggest to the psychiatrist how he can develop, among an untrained group of prison guards, adequate insight to carry out intelligently the few treatment suggestions which he may make. And this, it goes without saying, is an essential prerequisite to good psychiatric work directed toward the development of social attitudes in individuals whose previous conditioning has been along antisocial lines and who are only too eager to pounce upon their keepers' scoffing at the "bug doctor" as an excuse to avoid exposing themselves to any therapy he may be able to dispense. By implication, at least, Mr. Bates shows that

he is aware of this fundamental difficulty and indicates that its solution may be found in the present civil service system used in the federal service. He describes the training and promotion plan as being conducive to the development of a qualified personnel. With the exception of the chief administrator and two or three wardens, every member of the federal prison system is under civil service. Promotions are made from the ranks and study courses are provided for preparation for higher office.

The federal prison system as described in "Prisons and Beyond" now consists of 12 institutions graduated from work camps, with minimum security, through reformatories of medium security, to the widely publicized Alcatraz, a super-maximum security prison for incorrigibles and long-term offenders. The camps and reformatories stimulate our interest but it is difficult to imagine psychiatry accomplishing anything worthwhile in that forbidding island fortress which looms out of the fog of San Francisco Bay.

Is segregation the only answer to crime?

It has come to be accepted as such. But, as Bates points out, there are alternatives which may prove to be more practical, parole, probation, restitution and industrial colonies. Massachusetts, for instance, has twice as many men under probation as are in its prisons, and the Massachusetts' penal system compares favorably with that of any other state. The Russian industrial colonies appear to be showing favorable results.

The criminology of the future should be free of any notion of punishment. Punishment does not pay society. The sadistic thrill of a few individuals who enjoy a good hanging or the increased circulation of a sensational press indulging in an hysterical "crime drive" are too dearly bought to be tolerated. Sound economics, as well as humane thinking, demand that each offender be treated in accordance with his own potentialities and it is requisite that the forms of treatment available be as varied as is necessary to meet individual requirements. Perhaps we may even envision what might be a Corrective University of the future.

No consideration of crime would be complete without considerable attention to the problem of prevention. On this point "Prisons and Beyond" is lacking. But perhaps Mr. Bates' answer is expressed in his recent resignation as administrator of the federal prison system. He became director of the Boys' Clubs of America.

MARVIN SUKOV,
Chicago.

ESSAI SUR LA SCHIZOPHASIE. By *Jacques Delmond.* (Paris: Librarie E. Le François, 1935.)

In the study of abnormal, or for that matter of normal speech, one is faced with many obstacles and Delmond rightfully points out how difficult it is to take an objective attitude and to free oneself of certain established theories and to remain within the frame of the problem. With these apologetic remarks the author embarks himself on a presentation of a concept of schizophasia. He traces first the historical development of the problem. Schizophasia

as it is known was introduced by Kraepelin as a type of dementia præcox in 1910. Kraepelin described this group at that time as a form of dementia with confusion of speech. Since then cases have been reported by Teulié, Schiff and Courtois, Pfersdorff and Pandéroux and a few others. However, Bleuler felt that schizophasia is not a nosological entity since its elements are present in all types of schizophrenia. According to him it is merely the outward manifestation of the underlying fundamental forces and which are considered by him as physiogenic in nature, the psychogenic elements constituting the superstructure. Delmond espouses Bleuler's conception of schizophrenia and proceeds to develop in the present essay the concept of schizophasia along Bleulerian lines.

He defines schizophasia as a schizophrenic incoherence which he believes is a better term than the incoherence of dementia præcox because it is not only incoherence of speech or verbal incoordination or word ataxia but is the result of the fundamental disturbance of thinking. To Delmond this is also more in accord with the concept of Delacroix who defines speech as "the effect of the state of thought" and as "the creation of the total man." In schizophasia, he argues, there is over the verbal incoherence the conceptual incoherence, which are, of course, Bleuler's *Sprachverwirrtheit* and *Begiffverwirrtheit*, the two basic phenomena of schizophasia. What singles out schizophasia as a unity, according to Delmond is the verbal and thought incoherence, the fundamental incoherence conditioned by the primary disturbances which Bleuler defined as "the elementary weakness of the psychic integration—the association disturbance." Incoherence, according to Delmond, is what remains of the patient at any given time in the evolution of dementia præcox. It is a faithful witness of the psychic dissociation, of the intra-psychic ataxia or dysharmony (Stransky, Urstein). While schizophasia is not characteristic of any type of dementia præcox it indicates the intensity of the disturbance in the association processes. Delmond thinks that it first destroys those functions which are acquired with the greatest difficulty, with the result that only a certain word knowledge remains. It is not merely a chaos of syntax and ideas, not only a fragmentation of grammar but a conceptual incoherence. The author mentions Krafft-Ebing who believed that in schizophrenia the words lose their meaning and that they become, so to speak, empty envelopes. He also refers to Bleuler who disputed this conception and who suggested that the envelopes are filled with new contents. The question of neologisms is mentioned and the author rightfully feels that they should be considered as a part of the problem of schizophasia. But it is rather surprising that Delmond should minimize at the same time the importance of neologisms believing that not even a philologic analysis of neologisms will give the key to psychiatric problems. He thinks that neologisms are more or less well formed grammatically and often depend solely upon the cultural and the previous intellectual level of the patient. He enumerates the various modalities of schizophrenic speech, such as mumbling, unintelligible logorrhœa, affectation and bizarreness and the hyperkinetic verbigeration. Of particular interest is his discussion of the changes in intona-

tion with the monotonous type of speech or the speech which is colored by paradoxical affectivity. He also mentions the grandiloquent and the histrionic types of speech. Changes in timbre and the superimposed abnormal noises are considered. Other disturbances are the dyslalias with changes in rhythm and articulation. Here also belong the compulsive thinking with echolalia and palilalia; the impulsiveness with logorrhœa and verbigeration; the hyperkinesis with the tendency to endless recapitulations. As samples of verbal disturbances he mentions elisions and amorphous neologisms; in the nominal disturbances there are changes in the meaning of words; in the syntactic disturbances there is the so-called telegraphic speech and in the semantic disturbances the ambivalence, ambitendence, negativism, symbolism and approximation of thinking.

Using Head's method of examination of aphasic speech Delmond tries to analyze the schizophrenic speech at its different levels of disintegration. He singles out the verbal disturbances with the word salad or the jargon-aphasia, the nominal disturbances with the neologisms and paralogisms, the syntactic disturbances with the interpolations, the simple and complicated syntactical disturbances, the so-called paragrammatisms of Bleuler (the pure form of schizophasia), the semantic disturbances with the philologic interpretations and the dominations of the musical elements and the approximation of meaning.

Goldstein's concepts of the four types of speech are also utilized in the analysis of schizophasia, which all brings Delmond to the conclusions that there is a close relationship between the aphasic disturbances of organic origin, the speech in dementia præcox and the speech under emotional stress, fear and fatigue.

Delmond describes the methods he used in study of schizophasia and of particular interest are his phonographic recordings of the productions. This method affords registration of the rapidity of speech, the phonetic disturbances, the strangeness and many other phenomena which otherwise would escape analysis.

At the end of the review one is tempted to return to the author's introductory remarks in which he expresses the belief that speech is inseparable from all other acts of life and that it not only serves the purpose of communication but that "we express ourselves entirely in speech." Having gone so far one wonders why the essayist did not consider more fully the emotional forces behind the schizophrenic speech. All in all this is a welcome contribution. Such studies may bring us to a better understanding of abnormal and perhaps even of the so-called normal human speech which, should Sir Richard Paget be correct, "is still in a very primitive and barbarous condition."

J. Notkin,
Poughkeepsie.

THE MENTALLY ILL IN AMERICA. A HISTORY OF THEIR CARE AND TREATMENT FROM COLONIAL TIMES. By *Albert Deutsch*. (New York: Doubleday, Doran & Co. Inc., 1937.)

This is a book which may be characterized at once as indispensable for any one working or wishing to inform himself in the field of human welfare. The care of the socalled insane has always been a social problem; it is only within recent years that it has been generally recognized as primarily a medical issue. But with this shifting of emphasis which made possible the birth of modern psychiatry the problem of the mentally ill lost none of its social significance; rather the corrective reorientation stressed the social aspect: and since the question of treatment has always been the concern of the constituted authorities of larger or smaller governmental jurisdictions, psychiatry has hitherto been the sole branch of the healing art to be dealt with as state medicine.

The author of this history has accomplished an admirable research and has assembled a wealth of invaluable material which otherwise must have remained in large part inaccessible. He has presented the story to date of society's ways of dealing with the mentally ill, paying due attention to the administrative, economic, legal and medical aspects of the problem, and to the successive theories and motives which have actuated the changing attitude of governments and communities as humane and scientific procedures have gradually replaced repressive and fantastically brutal ones.

An enumeration of chapter headings will indicate the wide sweep of this work. Under "Prophets, Demons and Witches" the author supplies the necessary historical background, from the Egypt of antiquity onward, upon which to trace the development of the modern science of psychiatry. The outstanding names in Greek and Roman medicine and their contributions are passed in review, reminding us that much that is good in the views and methods of today is of Greek origin. The fantastic theories and procedures of the Middle Ages gave way in the revival of classical learning, and at length special institutions were built—presumably first by the Moslems—for housing mental patients. The first in Europe of which there is indisputable record was built in Valencia, Spain, in 1408.

After discussing the plague of witchcraft which blighted too many centuries (the laws against witchcraft in the United Kingdom were not repealed until 1736), Mr. Deutsch launches into the main theme of his book in the chapter on "Colonial America: the Old World Heritage." The colonists had brought with them the old-world traditions, reflecting the worst of mediæval thought regarding mental illness; add to this the low plane of medical knowledge generally during the colonial period (the first medical school in America was established in Philadelphia in 1765), and it is not difficult to understand the poor estate of the mentally afflicted prior to the close of the 18th century.

Therapeutic efforts would naturally be patterned after those of the mother land. Characteristic was the famous remedy for epilepsy horrifically named "Spirit of Skull," a vinous concoction of "moss from the skull of a dead man unburied who had died a violent death." Charles II in his fatal illness was given the benefit of this mixture. Provision for the mentally ill during

colonial times is fairly summed up by the author in the words: "Punishment, Repression and Indifference."

But the humanitarian movement of the 18th century was destined to bear fruit. Under the influence of Thomas Paine, Benjamin Franklin and notably the Society of Friends, experiments in social welfare were initiated in America and thought was turned to the improvement of the lot of the socially disabled.

Mental patients were accommodated, in the cellar it is true, in the newly completed Pennsylvania Hospital (1765), and at Williamsburg, Virginia, was opened the first institution devoted exclusively to the mentally ill (1773). The methods of treatment were harsh enough; they were lingering echoes of the punishment and repression of the earlier period but not of its indifference. That was the significant thing; the point of view had changed. Coercive and painful measures which we should now look upon as barbarous were at least thoughtfully applied, and with the sincere purpose of ameliorating desperate conditions of which medical science still knew so little.

We come to the chapter "Benjamin Rush—the Father of American Psychiatry." This great physician (1745-1813), fellow-townsman of Benjamin Franklin, was the first American teacher of psychiatry and author of the first American textbook on the subject, *Medical Inquiries and Observation upon the Diseases of the Mind* (1812).

The attention which through the influence of Rush came to be focussed upon the subject of mental disease and its treatment was due not alone to the fact that he was the first exponent of the subject in the American colonies, but perhaps much more to the fact that he was one of the foremost public men of his time. He was the most famous physician in Philadelphia, then the medical center of America; he was foremost in every reform movement, an educationist of great foresight, an advocate of temperance, an enemy of slavery. He was one of the signers of the Declaration of Independence. His proposal, still unheeded a century and a quarter after his death, of an institution for the education and training of statesmen as men in other professions must be trained before they can be regarded as qualified to practice, deserves to be considered along with Plato's discussion of the ideal state.

In the treatment of the mentally ill, although Rush did not emancipate himself entirely from the crudities and even cruelties of his epoch, humanitarian reform was still the key-note of his program. He was the first to enunciate clearly the doctrine of proper segregation of patients, of engaging men and women of better type to serve as attendants, of the use of occupation, exercise and diversion as treatment measures, of improvement generally of the living conditions of the mentally afflicted. In America, Benjamin Rush sponsored the reforms which Pinel stood for in France, Tuke in England, Chiarugi in Italy.

In a chapter entitled "The Rise of Moral Treatment" we are introduced to the further flowering of the reform movement extending roughly over the first quarter of the 19th century. The pendulum had swung well over. The gentle methods of Pinel, the peaceful atmosphere of "The Retreat" at York were having their transatlantic effects. Kindness and friendliness

were replacing chains. "To fetter strong madness in a silken thread" was the ideal of the Friends' Asylum, American counterpart of the York Retreat, opened at Frankford, Pennsylvania, in 1817.

By 1825 there were institutions for the mentally ill in nine states, Virginia being the only state having two. This handful of asylums could of course provide for only a small fraction of the total number of persons requiring care, and it was inevitably the dependent patients who were chiefly neglected.

The next quarter of a century was mainly one of "Retrogression." Society had become conscious of the magnitude of the problem of pauperism so largely contributed to by the indigent insane and defectives. Public officials were alarmed by the cost of asylum building, indigent and irresponsible persons were "passed on" from town to town or "dumped" in dead of night on neighboring communities, or they were auctioned off to individuals or families who would undertake to keep them at the cheapest rate, sometimes as low as 25 cents per week.

It was the epoch of the "Poor House." These catch-alls, few in number at the beginning of the century, multiplied rapidly during the 1820's, until by 1830 they were to be found in nearly every state in the Union. These receptacles, mismanaged and ill-maintained, housed indiscriminately indigents, defectives and insane of all ages; some of the reports of these places which one may read in this book are harrowing indeed. The "Poor House" was indeed a poor house; its cost was small and it was an exceedingly poor place in which human beings must live. While there were some exceptions, "the road that led over the hill to the poorhouse proved to be a *Via Dalorosa* for those unfortunate creatures driven along it."

During this time while one side of the social picture was dark, on another there was a remarkable outburst of optimism. While the fortunes of the indigent insane were at their lowest ebb those of their more fortunate brethren in the larger institutions were lighted with gold promises. From the hitherto pessimistic outlook for the future of the mental patient—"once insane, always insane"—the pendulum of prognosis rapidly swung through 180 degrees. It was no less a man than Dr. Francis Willis, physician to King George the Third during his recurring periods of alienation, who in the course of the parliamentary investigation into the King's illness boasted somewhat injudiciously that he had cured nine of every ten mental patients treated in his private asylum. Although ridiculed by other physicians of the time, the statement of Willis gave impetus to a movement which developed into a veritable "Cult of Curability," to which Deutsch devotes a separate chapter. Superintendents vied with each other in recording favorable results; they entered upon an amazing statistical race, the numbers of cures among discharged cases mounting steadily to 80 and 90 per cent. The bull's eye was finally struck in 1843 when Dr. William M. Awl, head of the Ohio State Lunatic Hospital at Columbus, made this entry in his statistical report: "Per cent of recoveries on all recent cases discharged the present year 100." This feat gained for the Ohio hospital superintendent the sobriquet "Dr. Cure-Awl."

The curability cult reached its peak about 1850, after which under accumulating protests and criticism it slowly waned. Its death blow was delivered

by Dr. Pliny Earle, himself previously a subscriber to the 90 per cent curability fallacy, who devoted many years to the patient study of hospital records and the assembling of reliable data. These he finally gathered together in his epochal book *The Curability of Insanity* (1887) which turned the tide of prognostic optimism into a more healthy channel. But it would be a mistake to regard the Cult of Curability as defunct. A few years ago the elimination of focal infections was credited with 80 per cent recoveries; and lately similar results have been reported in the insulin treatment of schizophrenia.

In a chapter on Dorothea Dix (1802-1887), the author presents a fairly detailed study of the life and magnificent work of this militant crusader of the mid-nineteenth century. Her zeal for improving the lot of the mentally ill took her from one end of the country to the other, and to Canada, Great Britain and the Continent as well. To her credit stand the establishing or enlarging of mental hospitals in 20 states, in several states of more than one. She was instrumental in the founding of the Government Hospital for the Insane at Washington. "In all, she was directly responsible for the founding or enlarging of 32 mental hospitals in the United States and abroad." In the estimation of her contemporary, Dr. Charles H. Nichols of Bloomingdale Hospital, Dorothea Dix was "the most useful and distinguished woman America has yet produced."

We are next introduced to the "Mid-Century Psychiatrists," and particularly to "The Original Thirteen," that distinguished group of hospital superintendents who met in Philadelphia in 1844 and founded the Association of Medical Superintendents of American Institutions for the Insane, now known as The American Psychiatric Association. The work of these founders was truly pioneer work. Psychiatric knowledge and practice had advanced very little since the days of Rush. It was necessary to resurvey the whole field, to bring together such factual data as were available, to set up standards in all phases of the work and thus lay the foundation for future progress and for the development of psychiatry as a scientific discipline. The foundation laid by "The Original Thirteen" was well and truly laid.

Brief biographical sketches together with the individual contributions of the founding fathers will be found in this chapter.

From this point onward the activities of organized psychiatry on this continent may be traced. Modern psychiatry dated from this period. The first modern textbook, Griesinger's *Pathologie und Therapie der psychischen Krankheiten*, appeared in Germany in 1845.

One of the most vigorously and often bitterly debated questions of the day, and indeed for many years, was that of non-restraint, first introduced at Lincoln Asylum, England, in 1837, and later developed by Conolly into a complete system of hospital management. Conolly's work *The Treatment of the Insane Without Mechanical Restraints* was published in 1856. The vicissitudes of the non-restraint doctrine are set forth in some detail. Today mechanical restraint is a thing of the past in all mental institutions deserving the name of hospitals. That it is still in vogue in some parts of the country is evidence of the painful slowness with which modern methods,

even the most obviously indicated and necessary, can become universally accepted and practiced.

A unique and highly significant feature of the social problem of mental illness has been the proposition that "the insane are the wards of the state," with the consequent evolution of "state care." The necessity of state care was virtually recognized in 1751 by the provincial legislature of Pennsylvania in the establishment of the Pennsylvania Hospital at Philadelphia, and by Virginia in 1769 in founding the Lunatic Hospital at Williamsburg. By the middle of the last century it had become evident, first, that in spite of a greatly increased building program throughout the country, the provision of accommodation for patients was not keeping up with the demand; second, that the poorhouse movement was not a solution, but rather a retrograde step. It was not until 1890 however, that the state of New York, after long years of debate, passed the State Care Act which was a triumph of progressive legislation and largely set the pace for progress elsewhere. Justly it may be said that with this act was inaugurated the modern administrative phase of American psychiatry. It established the principle that the state was responsible for the care of *all* its indigent insane, thus providing for the removal of all such cases from almshouses to state-maintained properly staffed institutions, the names of which it ordered changed from "asylums" to "hospitals," symbolizing in this way the treatment objectives which had superseded the custodial.

A county care plan as opposed to state care was adopted in Wisconsin and a few other states, but the majority followed the lead of New York; some 24 states have organized effective systems of state care. Too many states, however, are still in the backward column, with no well worked out administrative provisions for the treatment of the mentally ill within their jurisdictions.

Until near the close of the nineteenth century psychiatry enjoyed the unenviable distinction of being "the Cinderella of Medicine." It was cloistered within the walls of the large over-crowded public institutions; extramural interests and activities were almost non-existent; there was hardly any affiliation with other branches of medicine; it was distinctly outside the main stream of medical progress; its scientific aspect was relatively little developed, its contribution to medical literature meagre; therapy was largely of the expectant type; the provision in medical school curricula for instruction in mental diseases was woefully inadequate. The very name of the organized body of psychiatrists, "the Association of Medical Superintendents of American Institutions for the Insane," typified its isolation.

In this state of affairs the Association changed its name in 1893 to "the American Medico-Psychological Association," and in addition took a very courageous step. It invited Dr. S. Weir Mitchell to deliver the annual address at the semi-centennial meeting the following year in Philadelphia and to criticize "boldy and with no regard to persons." Dr. Mitchell carried out with painful thoroughness his "uncongenial task of being disagreeable"; indeed in some respects he overstepped the mark. The purpose had been served however, and the Association welcomed the stimulus to carry forward reforms and initiate new activities which it knew were long overdue. Or-

ganized psychiatric research was begun with the establishment the very next year (1895) of the Pathological Institute of the New York State Hospitals, already provided for in the epochal State Care Act of 1890. The changes which the four succeeding decades have witnessed have been nothing less than phenomenal; but they are familiar to present day readers and need not be recited here. Mr. Deutsch deals with them fully in his chapter "Psychiatry Emerges from Isolation."

His next topic is "The Mental Hygiene Movements and Its Founder." We have now reached the opening decade of the 20th century. It was the time of the "beginnings of organized preventive medicine." Within this decade arose four national welfare organizations whose objective was the conservation of health rather than the cure of disease. These were the National Tuberculosis Association, the American Social Hygiene Association, the American Child Health Association and the National Committee for Mental Hygiene.

While, therefore, as the author observes, "the social climate was propitious" for the inception of the mental hygiene movement the circumstances surrounding its origin and promoting its development were unique. No other movement in social welfare has been so intimately bound up from first to last with the personality of one man. The story of Clifford Whittingham Beers is well told in this book—his three years' incarceration (1900-03) in mental hospitals in Connecticut, his high resolve that the bitter experience of hospital abuses should be turned to account, his careful planning and consultations regarding steps to take, the publication of his autobiography *A Mind That Found Itself* (1908), the founding of the Connecticut Society for Mental Hygiene the same year, and of the National Committee for Mental Hygiene in 1909. The gradual expansion of the committee's work is carefully detailed—its war and post-war activities, the promotion of psychiatric social work, the child guidance movement, mental hygiene in prison clinics, in industry, in education. Concurrently there was taking place an expansion of the mental hygiene movement throughout the world; in 1928 came the establishment of the American Foundation for Mental Hygiene, and in 1930 was held in Washington, D. C., the epochal First International Congress on Mental Hygiene, attended by delegates from 50 countries exclusive of the United States and possessions, the first world assembly in history of all those working in the field of mental health. The idea of such a world movement for the sake of the mentally ill had taken form in the mind of Mr. Beers while still himself a hospital patient. In his dream he saw his ultimate goal before he had taken his first step. Visionary his friends regarded it. But this was one of the "delusions of grandeur" which came true.

It is too early to gauge accurately the full significance of the mental hygiene movement, but we may feel assured that when the history of twentieth century psychiatry comes to be written it will rank among the few great advances in this field, and we may agree with Dr. G. Alder Blumer that the name of Clifford Beers will stand "with those of Philippe Pinel. William Tuke and Dorothea Dix."

The subject of mental defect is set forth in a separate section including a survey of "Historical Backgrounds" and "Changing Concepts in Mental

Defect." Former and present day views as to the nature and causes of the disability are considered, together with its social significance and the various methods of dealing with it.

Another chapter is devoted to "Insanity and the Criminal Law." Here are reviewed the principal criteria which from time to time have been set up for determining criminal responsibility, culminating in the legal tests emanating from the famous M'Naughten case (1843).

Briefly the author refers to current abuses in the matter of expert testimony and to the disgraceful exhibition of the all too frequent "battle of the experts." While recognizing that the prevailing rules of criminal practice are primarily responsible for the situation he justly observes that psychiatrists "are not wholly free from blame, since they permit themselves to become parties to this procedure."

One of the most illuminating chapters is that which treats of "Our Commitment Laws." It is recalled that the earliest legislation governing the disposal of the mentally ill (the first New York State law dates from 1788) had nothing to do with the welfare or even the rights of the afflicted persons; it was directed solely to the protection of society from those believed dangerous to be at large—the "furiously mad" as the New York law put it. The various laws, sound and unsound, which have successively come into force in the several states illustrate strikingly the changing social attitude toward mental illness and incidentally the degree of public enlightenment as to its nature. While orientation has gradually shifted from the standpoint of protection of the public toward that of the welfare of the patient, there is still no uniformity and there are still too many shortcomings in current commitment procedures. The disgraceful trial by jury, for example, is still in vogue. "There is no ground for complacency in viewing the present state of our commitment laws. Progress still moves with the pace of a sloth. Obstructionist forces of all kinds still place barriers in the path of progress. . . . . Let us not be satisfied with the fact that the trend toward more humane commitment laws is evident: it is necessary to mobilize our forces for the rapid acceleration of that trend."

Discussing "Modern Trends in Institutional Care," Deutsch calls attention to the array of developments in therapy and institutional organization during the past few decades which have made the best of our modern hospitals what they are. He points out that these advances are far from uniform. "Standards may be poles apart in different states, or among hospitals within a given state." Twenty-five years ago Thomas W. Salmon remarked that "every stage in the long and painful history of the care of the insane from 1537, when the first institution for the insane in England was provided, could be actually witnessed in some American community this afternoon"—a statement which still contains much truth.

Psychiatry represents the original form of state medicine. With the setting up of the proposition that the insane are wards of the state and with the general adoption of the principle of state care, the practice of institutional psychiatry—the only psychiatry until the turn of the century—has ever been in some manner or degree under governmental dictation. Its belated progress as compared with other medical disciplines is in considerable measure

due to that fact. From the beginning it has had to struggle under the plague of political meddling and with the vice of the spoils system. These evils the author handles without gloves, with some unsavory illustrations from the past and some almost unbelievable features of political mismanagement in various states disclosed within the last three years by an enquiry conducted by the Committee on Standards and Policies of The American Psychiatric Association. The manuscript of this book was completed too soon to include reference to the latest major example of mischievous political interference, namely the recent upheaval in the state of Massachusetts.

In a final chapter entitled "Towards Mental Hygiene" the author endeavors to give a picture of present day psychiatry from the standpoint of psychiatry itself, with due reference to some of the great teachers who in the past four or five decades have virtually built up a new science. The first of these was Kraepelin, justly called the father of modern psychiatry. While paying tribute to the achievements of this great pioneer the author hardly does full justice to Kraepelin's foundation work. Those who have followed the successive editions of Kraepelin's monumental treatise will hardly agree that his conceptions were "static"; and that they were characterized by "extreme dogmatism" is an unfortunate misstatement.

The author takes note of the diversity of views and approaches which characterize the psychiatry of today in contrast with that of the end of the last century. The psychoanalytic school he treats with fairness, noting both the favorable and unfavorable aspects of Freudian theory and practice. The final pages are thoroughly up-to-date for they contain discussions of such new procedures as narcosis therapy, insulin shock and convulsive therapy.

It is impossible even in so extended a review as this to reflect the enormous research which has gone into the making of this work. The scope of this research is indicated in the 18 page bibliography at the end of the book which is conveniently arranged by chapters. Here are found not only the relevant treatises and professional works but a wealth of citations from local and state records, institutional archives and reports, court proceedings, reports of special committees, legislative enactments, society proceedings, government publications and periodical literature. It is the first time that such a body of information has been brought together and its value is very great. As a work of reference it may be consulted confidently by the writer or speaker on almost any phase of administrative and state psychiatry and mental hygiene; and it is to be hoped that it will find its way to the desks of all governing bodies of public institutions for the mentally ill.

A work of this kind should be required reading for the student of psychiatry to furnish him with a reliable and comprehensive historical background. It traces for him the development of the subject through the phases of neglect, custodial care, empiricism, research and rational therapy, and finally prevention, which is the keynote of mental hygiene. The real significance of modern mental hygiene can only be grasped by a knowledge such as this book supplies of the antecedent conditions out of which this great humanitarian movement sprung.

The book is well indexed and contains eight illustrations.

In Memoriam.

S. A. KINNIER WILSON.

1878-1937.

The death of Kinnier Wilson on May 12, 1937, removes from the neurological and psychiatric world an outstanding personality and a brilliant thinker.

Born in New Jersey, U. S. A., in early boyhood he came with his sister and his widowed mother to the latter's native home in Scotland. After his preliminary education in an Edinburgh day school he went on to Edinburgh University where he received both his academic and his medical education.

After graduation in 1902 he was house physician to Sir Byrom Bramwell, under whose inspiration he threw himself with wholehearted devotion into the study of neurology to which he was henceforward to devote his life.

After a period of study under Pierre Marie at Bicêtre and in German clinics, he began his connection with the National Hospital, Queen Square, London, where he was to become an ornament of that group of neurologists which has lent such distinction to British neurology. There he was respectively house physician, registrar, pathologist, physician for out-patients, honorary physician. His hospital connections, however, were not limited to the National Hospital. For a time he was assistant physician at the Westminster Hospital and later physician and neurologist to King's College Hospital, and was consulting neurologist of the Metropolitan Asylums Board which had control of the large number of mental patients under the care of the London County Council.

From the beginning of his activity he was continuously productive, showing in all his communications keen clinical observation, thoughtful analysis of the problems presented, a broad grasp of the literature of the subject and a masterly form of presentation. His great ability was soon recognized by the neurological world, but his world-wide reputation was established when he published in 1911 his doctoral thesis on "*Progressive Lenticular Degenera-*

tion: A Familial Nervous Disease Associated with Cirrhosis of the Liver." In this contribution he threw an entirely new light on the rôle of the corpus striatum and on its relation to abnormal tone and dystonic movements. His discovery opened up a novel field of investigation, and the study of extra-pyramidal disorders, so industriously cultivated during the past twenty years, received its primary impetus from this epoch-making work of Wilson. It was natural that the clinical condition which he had first so clearly described and analyzed should henceforth be associated with his name as Wilson's Disease. Further experimental investigations of the rôle of the basal ganglia were interrupted by the war, after which he continued with his clinical investigations which covered the broad field of neurology.

The quality of his work and his masterly style are perhaps most clearly displayed in "*Modern Problems in Neurology*" published in 1928, a collection of papers dealing with present day neurological problems and presented before various medical societies.

Another witness to his ability and breadth of view is *The Journal of Neurology and Psychopathology* of which he became editor in 1920 and which bore the very distinct imprint of his personality.

He lectured before many societies both at home and abroad. Foreign countries delighted to honor him, and he was a member of neurological societies in France, Germany, Italy, Poland, Austria, America, Japan and Denmark. He was president of the sections of Neurology and of Psychiatry of The Royal Society of Medicine. He was secretary general of The International Neurological Congress in 1935. He made several visits to America which were a source of great satisfaction to him and from which, with his keen sense of humor, he derived no little amusement.

The mere record of his professional work and accomplishments fails to do justice to his many-sided and complex nature. In his neurological papers one is at once impressed by his clarity of thought, his style of presentation, his happy phrasing, his lambent humor. He was a dynamic personality; he made a deep impression upon his students. His judgments were clear-cut and outspoken. He was intolerant of the second-rate and he showed by his example what was meant by the first-rate. He got great joy out of the many aspects of life, and those who partook of his genial hospitality

were left with the impression of a rare experience. With his great ability and driving ambition there were many situations which irked him but his energy and pertinacity enabled him to attain his goals.

It is a great loss to neurology that the final fruition of his labors, "*The Textbook of Neurology*" on which he had been at work for a considerable time, had not been finished at the time of his death.

He married the daughter of the late Dr. Alexander Bruce, of Edinburgh, the well-known neurologist, and the deep satisfaction of his family life gave a suitable complement to his brilliant professional career.

C. M. C.

THE CAMPAIGN AGAINST EPILEPSY.*

By WILLIAM G. LENNOX, M. D., Boston, Mass.

I shall attempt an outline of some of the main problems presented by epilepsy and also some of the essential elements in any serious effort to resolve them. I shall consider, first, the care and treatment of patients, as related to both the social and the medical aspects of the problem, and, second, research investigations which attack the etiological foundations of the disorder.

The Care of Epileptics: Social and Economic Problems.

A few statistics concerning epileptics will bear restatement. There are in the United States approximately a half million persons who are or have been subject to seizures. This is about the same number as have diabetes or active tuberculosis. Of the total epileptic population, about one-tenth, or 40,000, have settled out of the community and into state institutions. Of these only about one-fourth are in colonies especially designed for the care of epileptics. Epileptic patients occupy about 10 per cent of the beds in institutions for nervous and mental diseases. The annual cost of caring for these 40,000 epileptic patients is approximately eighteen million dollars.

This small army in institutions and the larger one outside constitute a considerable social and economic burden. This burden we must view not only as members of the guild of physicians, with our traditional circumscribed obligations and outlook, but also as members of society and as taxpayers. In the long run, medical efforts towards the physical well-being of man must mesh with the gears of society's social and economic needs. Granted this position, then a

* Read at the ninety-third annual meeting of The American Psychiatric Association, joint session of the Section on Convulsive Disorders and the American League Against Epilepsy, Pittsburgh, Pa., May 10-14, 1937.

This paper is No. XXVI in a series entitled "Studies in Epilepsy."

From the Neurological Unit, Boston City Hospital and the Department of Neurology, Harvard Medical School, Boston, Mass.

series of questions require answering. Is our society sufficiently rich and well organized so that everyone, regardless of whether he is useful or not, can be supported and medically cared for? If there are not enough sustenance and care to go around, should the productive or the nonproductive members of the hive have the honey? Or, phrased for the programs of medicine, should the amount of money and of medical attention which is given to sick persons be influenced by considerations of whether these sick can be brought to a state of economic self-support, and of social usefulness? We doctors attempt to persuade parents not to sacrifice their normal children in order to lavish love and money on the child whose mentality is beyond any hope of repair. Society seems oftentimes proudly to provide lifelong medical and nursing care for the hopelessly defective, and to leave the indigent but mentally normal patient to the chances of charity. In discussing the care of the handicapped, we should consider not only what is being done, but also what might be done if we could plan afresh and in the interest of future society, unembarrassed by tradition or political opinion. We should, however, acknowledge the limitations set by money costs and by the fact that someone must pay the bills.

In terms of prognosis for social usefulness, mental state is of more importance than the frequency or severity of seizures. On the basis of mentality, epileptics can be placed in three groups. The first and largest group—perhaps 60 to 80 per cent of the total—are patients who mentally are normal or nearly normal. Socially as well as numerically important, the great majority of this group are being treated by private physicians or in public clinics and hospitals. A minority, however, in numbers probably running into the thousands, because expert medical attention is not available, or home conditions are unfavorable, or because seizures are frequent, need hospital care. We physicians are at a loss to find a place for them where the cost is reasonable and where other patients and surroundings are stimulating. This first group comprises patients with an I. Q., say, above 80 per cent, a personality which permits living peaceably with other patients, and an outlook which, if seizures can be controlled, justifies the hope of a productive place in society. Each patient successfully treated at this early stage may save the community thousands of dollars in later institutional care.

For these patients, there should be moderate-sized hospitals near medical centers, which are adequately staffed and equipped for thorough examinations and for research, and which provide therapy, and mental and manual training. If, in spite of efforts, the intelligence or the behavior of a patient becomes definitely abnormal, he automatically should be transferred to a lower grade institution, as is the rule at Lingfield, England. Some of these units should be privately supported, permitting admission of patients across state lines. These home-hospitals for the forgotten patient would seem to be a better field for the expression of self-sacrificing devotion by religious organizations than the maintenance of expensive modern city hospitals.

Could some of these units for high grade patients be installed in existing colonies? I have the impression that the heads of colonies doubt the wisdom or the practicability of complete segregation of high grade patients. These form but a small minority, their services help to reduce running expenses of the institution, and the patients themselves are not adversely affected by contact with low grade associates. But relatives and some physicians do not agree to this last point. We are in need of statistical evidence concerning the effect on the mentality of association with much more deteriorated patients. Of course, simple segregation of high grade patients would avail little unless opportunity for manual or mental training and an atmosphere of hope and of expectation were also given them. On the educational side, the Detroit experiment of a sort of boarding public school for epileptic students is worth watching. We need work shelters—and organizations, as in England and South Africa—designed to find employment for epileptics.

To my mind a shining example of an institution embodying some of these ideals is Filadelfia, in Denmark. The studious and courteous Dr. Schou, who is combined administrator and investigator, presides over a 500-bed colony, morally backed by a semi-religious organization. He saves enough out of the 40 cents a day fee from patients to erect a building which is a combined guest house and research laboratory. The next meeting of the International League against Epilepsy will be at this lilac-surrounded institution.

I have seen but one private institution for mentally normal patients in the United States, the Emma Pendleton Bradley Home

of Providence, Rhode Island. In this home, epileptics form but one-fourth of the population of physically handicapped but mentally normal children. According to Superintendent Bradley, the progress of other patients is not retarded by the presence of the epileptics, and the latter benefit from association with patients handicapped in a different manner.

The second and next largest group are those patients who are definitely deteriorated, and short of some miracle can never again be useful members of society. They number perhaps 20 to 40 per cent of the whole. Yet they have once been fairly normal and even now are able to feed and clothe themselves and enjoy small pleasures, and do small tasks. Many, perhaps a third, are gathered in tax-supported institutions, where physically sheltered and medically protected, their lives are prolonged. The annual rate of turnover in epileptic colonies is 12 per cent, against 22 per cent for other state psychiatric institutions. The declining institutional death rate from tuberculosis and other infections is more of a pride to doctors than to taxpayers. I have visited most of the state colonies and have a high regard for the efficiency with which they are run. There should be more than 10 for these 48 states. For most of the patients sent to them, colonies are a haven of refuge from a cruel world; for society, they are an important means of reducing procreation and of providing physical care at a minimum cost. Opinion seems to differ as to whether a colony should be for large scale, custodial care of patients, or whether it should be in fact a hospital. I know that the medical officers of colonies struggle valiantly to keep their institutions hospitals, but may well despair in the face of a rising tide of permanently maimed and seriously deteriorated patients seeking admission. In one colony, the superintendent seems to be unusually successful in shunting the lower grade of cases to mental hospitals, so that the mentality of patients is, I believe, well above the average for colonies, yet funds permit the hiring of only two physicians for the 1200 patients. If modern medicine has nothing to offer to the lower grade members of this group, could they not be taken care of in separate institutions at an even lower cost than the present $1.20 a day? Freed of this burden, colonies could really be hospitals and could throw more support to the productive

part of any program, the care of those mild or incipient cases who stand the best chance of regaining a place in society.

The third and smallest group, numbering probably only a few per cent of the total, are those whose future is and always will be totally hopeless. These are the congenital imbeciles and idiots, the monsters (ugly mistakes of nature, matter in human form without human mind) which by no imaginative possibility can ever be anything better. Money now spent on this group, which is relatively expensive since the members require an unusual amount of nursing care, might better be given to needy members of the first group. And here we, physicians with inherited ethical standards, give way to a biologist and quote Raymond Pearl:[1] "These unfit organisms are kept alive by the rest of society for no realistically demonstrable reason other than that they were once born, and by being born, somehow placed upon the rest of mankind what has gradually come to be regarded as a permanently binding obligation to see that they do not die. It is difficult to convince a biologist that a social philosophy will endure for any great length of time that deliberately and complacently loads upon the already weary backs of the able and fit an evergrowing burden." We at once remind the biologist that, though the physically and mentally unfit are useless, the criminal groups are actually harmful to society and logically should die doubly soon. Yet I see the ghastly incongruity of a society which systematically and cruelly kills its best members by the means called "war," and unmercifully prolongs the lives of its hopeless liabilities. Bullets for the best of humanity; preventive inoculations, trained doctors and nurses for the worst.

In addition to these considerations of responsibility and of hospitalization, concerning which we each have differing opinions, I believe we would all agree that there is need for a changed attitude of society towards epileptics. This altered attitude should originate with physicians, many of whose ideas about epilepsy are long out of date. I quote from the advice given by John of Gaddesden from a book printed in the year our continent was discovered. "Epileptics," says John, "should not mingle with the people to any extent—otherwise this becomes the 'convivial disease' since it occurs at banquets and in crowds on account of the breaths of men which are increased in the brain of the patient, and on account of the

presence of his betters whom he fears and before whom he is ashamed, and by thinking of his condition in their presence, he falls."

The healthy "betters" of the middle and early ages had reason to express disgust, and epileptics had reason to feel degraded, for were they not devil possessed? Now we have no such excuse. Education of physicians and of the public to the view that convulsive seizures are no more shameful than attacks of migraine or of dysmenorrhea, and that the probability of transmission is no greater than that of the transmission of diabetes, is one of the functions of an informed minority, such as we are.

The economist, who has some idea of practicing economy, is never popular. We are glad to turn from sociology to medicine.

Medical Treatment.

The standard means of diagnosis and of treatment are well known to careful and conscientious physicians: careful history-taking; detailed physical and neurological examinations fortified (in special cases) by encephalography; elimination of abnormalities; control of the convulsive manifestations (if they exist) by sedative drugs, or in certain cases, by ketosis or dehydration, and (oftentimes the best rewarded of the doctor's efforts) support of the patient in his effort to maintain his morale and his place in society. What we know is indeed woefully inadequate, but if the above short guide were carried out by general practitioners and so-called "specialists" throughout the country, epileptics would be a much happier and a healthier group of patients.

A considerable proportion of patients look to patent medicine houses for their treatment. Recently I have written to a number of patients who gave testimonials for the principal mail order concern in the United States, and I have visited the physician who is in active charge of this business, an M. D. who graduated near the top of his class in a grade A medical school. This concern is, I believe, in position to offer serious competition to the prescription-writing type of doctor. If these doctors do no more for patients than Dr. James does (ask some questions and give phenobarbital), it is not strange that their services are undersold. Aside from informed conscientious treatment of the patients by the doctor, the

chief cure for quackery is education. Newspaper headline writers must in some way be taught that every report coming from a laboratory is not a "cure." Doctors and patients alike must be kept from reading textbook discussions of epilepsy more than 20 years old. An extended and critical review of the literature should be made periodically. There could be a layman's division of the American League, the members of which would receive annually a nontechnical digest of the review.

Investigation.

Our hope of really helping epileptics lies in the uncovering of new facts and new methods of treatment. What is being done, what should be done, and who will pay the bills? In the past two years, I have visited workers in 25 cities. I cannot here attempt even an outline of work planned or going forward but I believe that never before has there been so widespread an interest in research on the problems of epilepsy. Elsewhere [2] I have set down some of the reasons for believing that epilepsy is a fertile field for research. I shall touch but briefly on some of the main objectives in the search for the causes of epilepsy.

1. The end of research is the eradication of epilepsy from the human race. Evidence is abundant that an inherent though recessive quality, the seizure predisposition, is fundamental. The epileptic is but one of many who possess the predisposition, the gene which may result in paroxysmal cerebral dysrhythmia. In the presence of a given stimulus (birth injury, cerebral infection, trauma) or even without apparent stimulus, the predisposed individual will have seizures; the unpredisposed will not.

There is evidence that genes are chemical substances, perhaps a single large organic molecule. In the end, we must eliminate this molecule or learn to alter its chemical structure. Two roads lead to this goal: First, the breeding out of the abnormal gene; second, its alteration through direct chemical means. The first method will require social human planning and thousands of years of time; the second will require a knowledge of how to alter small chemical units of the body, a knowledge which we do not possess. Tantalizing is the thought that epilepsy could be eliminated from the race by the replacement of, say, a potassium for a sodium ion on a certain

molecule, the total bulk of which molecules for all persons living on the globe is not larger than a mustard seed. However, we are like elephants set to repair a wrist watch; our minds are too small and our hands too huge for successful tinkering with the ultramicroscopic wheels of life. The fact that genes can be altered by exposure to X-ray (even though this has a mutilating effect) gives a shred of hope that some day in some generation a way will be found. For the present, there is some satisfaction in trying to see the final goal, even though, like Moses viewing the Promised Land, we know that we, personally, shall never possess it.

2. Elimination of seizures from individuals. This nearer goal seems not unattainable. It involves alteration not of the chemical molecule which is the gene, but of the gene's abnormal product, the chemico-physical structure of the neurones of the brain. The easily recognized asymmetry of features and of body measurements of epileptics may be matched by invisible asymmetry of the molecules in brain cells. Demonstration that a seizure is a disturbance in the normal rhythm of the electrical activity of the brain permits concentration of attention on those elements which have to do with electrical discharge; namely, the concentration of electrolytes, of oxygen, or of sugar, and the pH of the brain cells, and also the permeability of the cell membranes. The fact that various alterations in body chemistry, such, for example, as simply increasing the CO_2 concentration of respired air, suppresses the abnormal electrical rhythms of epilepsy, indicates the possibility of influencing cell chemistry by clinical means. However, such procedures have not yet revealed the specific abnormality in the neurones of epileptics. Overventilation of the lungs will indeed induce seizures, but only in those patients who are subject to seizures.

The demonstration of the specific chemical abnormality is the most important but most difficult problem before us. The disorder is exactly comparable to disorders of cardiac rhythm, paroxysmal tachycardia, for example. Cardiologists are content to say "irritability of the cardiac pacemaker." But we cannot be content until the process which causes "irritability" is known and controlled. So far, physiological and chemical studies have dealt with body fluids and with organs distant from the brain. We must be able to work with brains of living patients. Advances in surgery make this more feasible than it once was.

Study of Nerve Physiology.

Discovery of the specific something in the physiology of nerve cells which makes them discharge in abnormal rhythm may require many years. We can be greatly heartened by recent enlargements of our knowledge of nerve activity. Already neurophysiologists have demonstrated chemical mediators of nerve impulses, the dependence of electrical discharge of cells on the concentration of certain ions within and without the cell, the influence of ions on the oxygen metabolism of brain cells, the dependence of the principal ion, potassium, on the activity of the adrenal cortex, and the influence of changes of pH, oxygen tension, and sugar on the electrical activity of brain and nerve. These laboratory studies are in close agreement with clinical observations of the last decade, which show, in general, that chemical changes which accelerate the discharge of nervous impulses, also increase the frequency of seizures, and vice versa.

Epileptics are not and never will be simple nerve muscle preparations. The neurones of the brain are connected with and influenced by other portions of the body, especially the nourishing currents of blood, the secretions of glands which are poured into the blood, and perhaps of most importance, the outlying garrisons of the nervous system called "the autonomic nervous system." The chemical mediators have a special clinical significance because of the possibility of neutralizing or counteracting abnormal impulses in the course of their passage from the neurone to the muscle. Even if the evil emissary cannot be prevented from setting out on his journey, perhaps he can be thwarted before he has delivered his message.

Intricate investigations of this type involve the use of special techniques and of especially gifted technicians. The deep problems of epilepsy, as of ills such as cancer and old age, belong to men in laboratories, who are assured of adequate support over a period of years. Our big concern is for men with ideas, and with the energy and the devotion required to put them in execution. The tide of American revolutionary morale turned with the arrival of Lafayette. Just so we embattled epileptologists have reviving courage because of the timely arrival of neurophysiologists like Gibbs and Spiegel.

Indirect Contributions.

Although great and easy victories gained by practitioners of medicine working single-handed are of the past, much of value can yet be learned by keen and honest-minded clinicians. The shining crest of a Mt. Everest can be reached only by an individual extraordinarily endowed by nature but he will reach no such summit unless supported through the various stages of his climb by fellow climbers, technical assistants, and bearers of burdens. The problem of epilepsy offers many opportunities for significant pieces of work which do not require expensive apparatus. However, it requires willingness to do honest and long-continued work, to accumulate sufficient data properly controlled and to integrate and interpret these data in the light of contributions by others.

In our colonies for the care of epileptics, we have collections of human material not to be matched elsewhere. Many valuable contributions have come from some of these colonies. But personnel and funds are limited and while waiting for legislators to realize the money-saving possibilities of medical research, colonies can render a large service to investigation in two ways: first, the resident staff can make large scale test of ideas concerning therapeusis developed in research centers; and second, the management can invite adequately equipped and financed groups from these centers, who will reside in the colony for short periods of time and make studies which the colony itself could not undertake. We workers at Harvard owe much to the hospitality of Dr. Hodskins and his staff at Monson, and also to Dr. Renner, Dr. Marsh, and Dr. Shanahan and the respective colonies over which they preside.

Though investigators equipped with ideas are of first importance, money is also a necessity. I have found only four localities where money has been especially designated for work with epilepsy, Chicago, Baltimore, New Haven and Boston. The total annual amount available is only about $15,000. Income from the largest fund, the $200,000 Minnie Frances Kleman Memorial Fund in Chicago, is for the "assistance of indigent patients suffering with epilepsy," without specifying their locality. The funds at Johns Hopkins and Yale are likewise the income of endowments but limited to those universities. The Harvard Epilepsy Commission has no endowment, only contributions from interested persons.

Most of the research now being conducted comes from foundations and from general research funds of schools and hospitals. I doubt, however, if the whole amount spent on investigation of epilepsy in this country amounts to one-tenth of one per cent of the cost of caring for epileptics. Because of the avowed New Deal policy of liquidating large private fortunes, which have in the past been a principal source of endowments for foundations and schools, medical research, including that for epilepsy, faces a curtailment of activity unless new sources of supply can be found.

In the long run, the people of the United States are the benefactors from medical research and presumably must pay either involuntarily through tax-supported agencies, or voluntarily in multiplied small amounts. Those who are most immediately benefited by research should be the first to give. In order to gauge the reaction of patients to a request for contributions, I have adopted the plan of adding 5 per cent to the bill of each private patient. The following printed notice accompanies the bill:

> In order more effectively to treat diseases such as the one for which you have consulted us, further investigation is essential. With the financial support of interested persons, we are actively carrying on such research. It seems to us that patients who have benefited from previous research or who may benefit from investigations carried on in the future will be glad to contribute to the search for better methods of treatment. We are, therefore, adding 5 per cent to the bill of each of our patients for this purpose. It is understood, however, that payment of this item is entirely voluntary. Do not include it in your check unless you so desire.

In the year in which this practice has been in force, every patient has paid this item without question, and a few have voluntarily increased the amount, so that an average of more than 10 per cent has been received. I believe the principle has received vindication and the practice is worthy of extended adoption by doctors actively engaged in investigation. Then foundations and wealthy persons, while they last, should be shown the need and the opportunity for investigation in this neglected subject of epilepsy. The most permanent of organizations, and the most to gain by reduction in the numbers of epileptics is government itself. Against the present eighteen millions spent by state governments for prolongation of the life of epileptics, only Michigan provides a fund for finding new methods of preventing or of shortening the disease. Public

authorities seem to say, "Millions for maintenance, but not one penny for prevention."

The Need of Coöperation.

I have sketched the raw outlines of some of the aspects of the problem which confronts us; we have a Goliath of a problem and are but a small David going out to meet it.

The Chinese have a proverb:

> Three men with hearts together
> Yellow dirt changes to gold.

The International League Against Epilepsy has been reorganized with branches in five countries. Across the salt water, Dr. Schou, Dr. Muskens and Dr. Fox are trying to stimulate and organize interest. The periodical *Epilepsia* has been revived. We have a comparatively easy task on this big continent. The American Branch now numbers more than 100. Workers in certain centers in America are planning to pool their ideas and to investigate cooperatively certain aspects of the problem. The older, more specialized group, the Section on Convulsive Disorders of The American Psychiatric Association, and the young American League Against Epilepsy, are not competing, but are complementary organizations and should work together at a common task. We are a group huddled over a pile of wooden pieces of various outlines. The problem is to fit these pieces together until they make a picture. Our predecessors from Hippocrates downward have done their part—we add our newly gained knowledge to theirs. Our descendants will match other pieces and eventually the whole problem of epilepsy will be solved.

The immediate objectives of the campaign against epilepsy are:

For society—an awareness of the magnitude of the problem, of the present neglect of incipient cases, and the necessity for research.

For us physicians—a wider diffusion of present knowledge and a harder search for new knowledge, and a will to work together towards a common end, the end of epilepsy.

PROGNOSIS IN MENTAL DISEASE.*

The Use of One-Page Abstracts.

By EARL D. BOND, M. D., and FRANCIS J. BRACELAND, M. D.,
Philadelphia.

In the minds of the laity and, unfortunately, in the minds of many of our professional brethren, the prognosis in mental disease is a lugubrious one. They have supposed that anyone "unfortunate enough" to have been a patient in a mental hospital must henceforth be regarded as a semi-invalid and liable at any time to a return to his symptoms. While they have been unable to find a sign over mental hospital gates bearing the inscription, "All ye who enter here leave hope behind," nevertheless they have tacitly assumed that it could well be there. It is our purpose in this paper to examine the truth of these beliefs and to this end five year follow-up studies have been done on over 700 consecutive patients who were admitted to our hospital over a period of two years.

Before beginning this, however, it might be well to quickly scan our previous reports because they have been well preserved. Some of our statistics date back to 1751. From the earliest beginnings of the hospital till the end of 1928, we find that there were 23,146 admissions. Of this number our reports show that 7755 were discharged recovered and 6573 were discharged improved. Upon totalling the two we find that mental patients have not fared so badly after all. We spare you the arithmetic because the paper is to be rather heavily laden with statistics. It is evident, however, that even long before the advent of the newer types of therapy over 25 per cent of our patients were considered—at the time they left the hospital—to be recovered and another 25 per cent improved. We do not know how this number of consecutive admissions compares with the consecutive admissions of general hospitals because statistics of this latter type are singularly absent; however, when we compare our figures with the legends that have come down to us about mental patients we feel that they are much more comforting.

* Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pennsylvania, June 10-14, 1937.

For all patients, voluntary or committed, who were admitted to the Pennsylvania Hospital during the years 1927 and 1928, abstracts were made out on one side of an ordinary case record page. These abstracts magnified family history, pre-psychotic personality, life events, onset of psychosis and follow-up for five years after admission to the hospital. They minimized the symptoms shown in the hospital unless they threw light upon the earlier life history. As this is entirely a private hospital the families supporting these patients were able to give better than average histories and were easy to reach after the patients went home.

For these one page summaries we are sure there is a use in psychiatry. They allow us to present not statistics but abstracts which show individuals at a glance. It gives a view comparable to that of the low power of the microscope in which some relationships are seen which escape the oil immersion. Here is an illustration:

7433. Mr. S. W. R. Admitted 10-24-27. Dementia præcox—improved.
Father had convulsions to age 13, always sickly; a minister.
Paternal aunt had hysteria and "lots of imagining."
Patient is fifth of six children.
As child healthy, normal, "quickest of all the children."
In dentition very sick: strabismus developed which is now corrected by glasses.
At six to school; bright through high school and normal school.
Pleasant, kind, athletic, modest.
From 21 to 25 taught successfully.
At 25 entered a university: attended all social affairs.
Quiet and bashful, hard to get acquainted with.
Always one or two strong friendships with men.
"No time to bother with girls" or religion.
Clean, particular, exacting and methodical.
At 25 begged rides to Chicago: saw a clerk stealing and rode with a bootlegger.
Both he and companion saw bootlegger give signals and gave themselves up to police for protection.
On return he thought papers were stolen from his room and "broadcast": restless, depressed.
At 26 before admission hallucinated: "I am God." "I am I."
At 27 admitted to hospital: "They scoffed the Inferior." "Truly he was the Creator of all Laws": active and noisy.
Ideas of persecution became stronger.
At 28 discharged unimproved.
At 32 at home, "supporting himself, constantly improving as mother lets him alone. At times he is mildly upset." (From family physician.)

It is easy, when the abstracts can be read at a glance, to put them together in any way which seems profitable. Let us group them in this order:

I. Certain people who seem to have had everything against them from the start.
II. Certain others who seem to have had a very good start in life.
III. Certain people who were tipped over by apparently superficial causes.
IV. Certain others whose troubles, even in these short abstracts, seem to lie in deep instinct difficulties.
V. Cases which present complications and side-lights.

Now let us give you samples of "experiments of nature," knowing that you will not only read between the lines but read in also your own experiences. The one-page abstracts make it easy to group cases by any common factor.

I. We turn first to some people who seem to have been doomed from the start, in whom all of the conditions seem to have been right for the onset of mental disease.

1. Here is a man with a brilliant, alcoholic father; a maternal uncle who was psychotic; a mother who was brilliant, a suffragist, unreliable and emotionally unstable.

The patient dreadfully spoiled, tied close to his mother; was precocious with a tremendous inferiority complex. He always had large plans but he thought that work planned was work done.

Exhilarations came whenever he was given any recognition or whenever life for the next few days seemed hard or monotonous. Spells of despondency, always short, alternated. At 48 he is in a state hospital, never holding to the normal long enough to make it worthwhile to get out.

2. And here is a woman, with much mental disease in the family always delicate, one ear deaf, pitied, pampered and sheltered by relatives, but never allowed to carry out any plan of her own, depressed as a little girl, dependent on an older sister, but dominated by a disorderly emotional mother, her own warm and passionate nature frustrated.

In spite of sister's marriage, mother's death, 20 attacks of depression from 20 to 41, this woman now doing well as a trained nurse.

She was doomed to mental disease, but not to an entirely unhappy life.

3. Now we turn to a boy. Both paternal grandparents were psychotic; father and mother were brilliantly erratic.

He was a fat, croupy, rickety baby; a seclusive small boy, autoerotic, immensely scrupulous; precocious in college; he faced life with a brilliant intellect which carried him through college, but no further; worried about the danger of homosexuals in Europe, to which country he made a sudden trip.

On this trip immoral people signalled to him, noticed that his face was red and knew from this redness that he masturbated; on his return he was catatonic and preoccupied with dreams about a girl cousin, with somatic delusions, desperate anxiety to prove himself manly, which perhaps led to the only suicide among these 116 schizophrenic cases followed over five years.

II. In looking at the opposite of the unhappy early situation we turn toward many patients who got off to a very good start. The stage seemed set for a happy life. The simplest of all the histories will illustrate this.

1. A man of good family history, a steady worker, the secretary of his church, a 32d degree Mason, was happily married at 21, and very proud of his son. At 18 he had had gonorrhea; at 32 there was a urethral discharge which bothered him, and at 42, after a diagnosis of catarrh of the bladder, with reassurance that it was harmless, he began to sit looking for hours at a specimen of urine and saying that he had committed the "unpardonable sin." After a year's depression he recovered to hold a very responsible position for the five years to the present. Out of 47 years he has had one bad one. He was wounded in the heel of Achilles.

2. In another case the outcome was not so good. There was a negative family history; after the patient's illness a married sister became psychotic.

A normal usual childhood; a lovable, self-sacrificing and helpful boy; a good mixer, an athlete; popular; with a good sense of humor; he was president of his club; won the highest honors in his high school class.

At 26 he was shocked by the accidental death of his father; he sat and stared and wept. Gradually he became quiet and preoccupied; complained of his health and of plots against him. Paranoid and somatic delusions persisted, with hallucinations, and ushered in a seclusive and indifferent attitude which has lasted five years. He now goes about unkempt, unshaved, laughing in a silly way to himself.

III. Going one step deeper but still keeping to an apparently superficial level we have:

1. A man who was a very steady worker as a machinist for 14 years. At 35, after great fatigue on overtime work, he sought three escapes—he began to drink, he changed his work, and he became depressed. At 47, after whooping cough, he had another depression. "It's as if a heavy curtain were hung on my head, just as in a theatre, beyond which are beautiful things which I know are there but cannot see."

Or

2. Another man who simply had depressions six times after losses in the stock market; his average attitude being that of a braggart, a restless Lothario.

IV. And then, even in these low power views we get glimpses of deep "instinct troubles."

1. A shy, overmodest, autoerotic boy, interested only in serious things, was dominated completely by his mother (although his sister broke through a similar domination), who conquered his will with a rod. When he broke down at 26 he feared homosexuality and wanted to sleep beside his mother.

2. A kind, determined, athletic homosexual young man who limited his diet to salads and fowl, suddenly broke his engagement. He began to show his mother an affection which was very childish; he slept with her to protect her; voices told him that she was dead, or that she was immoral. At the hospital, he repeated "kiss mama" for hours.

3. A brilliant cheerful boy who became a fine student, a research worker, exceptionally clean and meticulously dressed. While sociable in a crowd, he had no intimate friends, never went in for love making, had his doubts centered upon women and marriage, and was very close to his mother. After some years of delusions he thought that he was hermaphroditic and decided that his refusal to act in sex had spread into all parts of his life.

4. A parallel case is that of a girl who had a strong sex urge, a frank interest in boys, a desire for admiration. She was voted the most popular student in her high school. After being a bridesmaid for her fiance's sister, and having sexual relations with an unknown man, she broke her engagement. She dreamed that her father's head was put in a bucket; she was the illegitimate child of Joseph and Mary; she dreamed that her mother was pressing her abdomen and her father rushed in—he was so closely identified with her that he sensed her pain. She said, "I thought I'd make over a man and I found he was my father." After a "marvelous healing in Christian Science" this woman was readmitted to the hospital.

V. What complications can come into case histories is suggested by the following:

1. A man with psychotic heredity, whose wife was psychotic, had his first attack at 43. He was hypomanic. Five years later he was depressed and brought to the hospital, where his spinal fluid was negative. Recovering from his depression he was discharged, but he returned in eight months with a fully developed Parkinsonism.

2. A man, seclusive and conscientious, married at 19 a wife who was pleasant and uncritical and who kept him in a good social current; even though he was depressed at 39 he kept on at work with his wife's help. At 48 his wife died and at 49 he married a woman who was critical of him and who expected him to fuss about her. The next year she had an operation and the patient went into a depression, at times agitated, at times retarded, which has gone on for five years. This case comes near to showing nature controlling her own experiment.

Diagnosis of the Present 710 Cases.

We have used the Revised Classification of Mental Disorders (Statistical Manual, 1934), and we agree that it is the best classification to be had at present. We have the benefit of the records of staff conferences on each case and also the added advantage of making the diagnosis five years after admission with the opinions of other hospitals and psychiatrists in the follow-up period to guide us. Nevertheless, we are far from satisfied with our diagnoses even after we have built up a large unclassed group. Some cases show more than one psychosis; some seem very definitely placed exactly between two groups. We have done the best we could and when a case seemed to be very close to one group it was included in it. There is nothing we should like better than to have two other psychiatrists divide these cases into groups and then to have the privilege of criticizing their arrangement.

Perhaps it would be well at this time to say a few words about the group which we have labeled "miscellaneous." This includes two epileptics, eight mental deficients, and one traumatic psychosis. We did not follow up this group because we had such a small number of cases and because the work on mental deficients and epileptics has been well done by other investigators. When we consider that only one case of psychosis due to trauma was admitted to our hospital in a period of two years it seems to confirm the prevalent notion that this type of illness is exceedingly rare. Unfortunately our one traumatic case returned to his own country and is lost to us as far as follow-up work is concerned.

Likewise we did not follow alcoholic cases or drug cases who did not have psychoses.

We are not considering the behavior disorders of children at this time. Admissions under this heading totaled 37, most of them following encephalitis. The reason for this apparently large number was the existence of the Franklin School and our findings were the subject of a previous study.[1] However we did follow the cases of adults whom we had diagnosed "psychoses with epidemic encephalitis." They were eight in number and of them we have the following to report:

Recovered	1	Unimproved	2
Improved	1	Died	2
		Lost	2

The one recovery is apparently genuine for we have recently seen the patient and she seems to be in splendid health and is still engaged in teaching school.

In all there were 710 cases admitted in the two years in question, divided as follows:

Manic depressive	171
Dementia præcox	116
Psychosis with somatic disease	60
Senile and arteriosclerosis	50
Involutional melancholia	47
General paresis	38
Alcoholics (without psychosis)	31
Alcoholics (with psychosis)	10
Psychoneuroses	37
Miscellaneous	11
Psychopathic personalities	8
Psychosis with epidemic encephalitis	8
Drug addicts	5
Paranoid conditions	9
Behavior problems (children)	37
Unclassed	72
	710

Manic Depressive.

It will be noted that there were 171 cases diagnosed manic depressive psychosis who were admitted for the first time in the period covered by 1927 and 1928. This constitutes approximately 24 per cent of all admissions and is in marked contrast to some of the reports received from foreign countries, notably Switzerland. In a report from the Burghölzli Anstalt in Switzerland covering a period of one year, we note that there were 11 patients diagnosed manic depressive out of 735 admissions or 1.5 per cent, almost a negligible quantity. Difference in racial characteristics in addition to different diagnostic criteria account for most of this discrepancy.

Our findings show that out of a group of 171 patients the results were as follows:

Recovered	86	Unimproved	30
Improved	19	Died	12
		Suicide	12
	Lost	12	

If we exclude the number of patients who died and those whose whereabouts are unknown, it could be said that 105 were improved after a period of five years and 30 remained either unimproved or suffered a recurrence of their illness. It is also noteworthy that 12 of the 171 patients were known suicides. We have no way of telling how many of those who were reported as having died a natural death, assisted themselves to that end. This confirms the already well known fact of the great suicide risk of depressed patients. The patients marked "recovered" are back in society and leading useful lives. The ultimate prognosis is not within the scope of this paper but suffice it to say that they have been normal and economically valuable for the last five years.

Involutional Melancholia.

There were 47 patients diagnosed as having involutional psychosis. In general the following criteria were demanded before making this diagnosis. First, that the patient be within the involutional period, that this be the first (and only) illness and that they have an agitated depression. We also included under this heading the paranoid types which occurred in the involutional period. The recovery and improvement rate here was perhaps a little higher than we had formerly supposed as is evidenced by the following:

Recovered	12	Unimproved	10
Improved	10	Died	13
		Lost	2

Of the 13 patients who died two were definite suicides, which is striking when we consider that out of 24 deaths in the manic depressive group 12 were suicides. Perhaps this can be partially explained by the fact that when patients have involutional melancholia and come under treatment they are usually continuously protected, whereas in the case of patients with manic depressive depressions, protection is withdrawn at the end of one attack and not resumed soon enough at the beginning of another. It should be kept in mind that our figures in this group encompass a time which antedated the present vigorous treatment with endocrine products. What the results of this latter therapy will show will make an interesting problem in the future.

Dementia Præcox.

The recovery rate in dementia præcox without specific treatment naturally holds unusual interest for us this year because of the attention that the insulin shock therapy is attracting. It should be kept in mind that some investigators now feel that with this new type of treatment, 80 per cent of recent cases can be helped to recovery. Of cases diagnosed dementia præcox * from the vantage point of five years after admission, full recoveries make up only 10 per cent. If to these are added cases which have improved to a considerable extent, the percentage of recovered plus improved cases is 31 per cent. These percentages may be increased if, to the cases diagnosed dementia præcox, there are added those which at one time or another and especially at the time of admission had symptoms which strongly suggested the diagnosis. In the manic depressive group there are 7 of these; in the unclassed group 16; in the paranoid group 5; making a total of 28. Of these 17 recovered, 3 improved, 3 were unimproved, and 3 were lost. By combining these cases of suggested dementia præcox with those which seemed fully to warrant the diagnosis the percentage of full recoveries is 20 per cent, and of recovery and improvement together 40 per cent.

Even stretching matters in this way the recovery rate is far under Dr. Sakel's 80 per cent. However, Dr. Sakel applies his recovery rate to patients who have been ill six months or less at the beginning of the treatment. In our cases of dementia præcox which had only been sick six months or less before admission, 11 per cent recovered. It is 10 per cent or 11 per cent of recoveries with which the results of insulin-shock treatment should be compared. Previous to this type of treatment there was no sustained form of therapy for schizophrenia which produced uniformly good results. In the past five months in our own hospital we have discharged patients as recovered after insulin therapy whom we would for-

* A report of the Burghölzli Hospital (mentioned two paragraphs above) gives the following statistics for 1936: all admissions 990: of which 11 are manic-depressive and 375 are schizophrenic. Diagnostic criteria are so different in Switzerland (and Vienna?) from those in the United States that allowances must be made.

merly have considered hopeless. The following table gives our findings in a five year follow-up study.

Total number of dementia præcox cases			116
Recovered	12	Unimproved	66
Improved	25	Died	10
		Lost	3

General Paresis.

One of the remarkable things about the reports of this group is the paucity of its numbers. It is apparent that the number of patients with paresis admitted to private hospitals was already beginning to dwindle at this time. This lessening has continued steadily and during the last 10 months not one case of paresis has been admitted to our hospital. True enough, on our wards in the city hospital admission of patients of this type are still plentiful. The reasons for the decreased admission of these patients to hospitals like ours are not entirely bound up with a marked drop in the incidence of the disease or even with an increased efficiency in the method of treatment. Some of it is also due to the fact that many general hospitals have taken on the treatment of paretics and as a consequence only the very noisy or unmanageable patients filter through to us.

There were 38 paretics admitted in the years 1927-1928.

Recovered	13	Unimproved	5
Improved	9	Died	12

Grouping them together we could say in a general way that 55.+ per cent improved and 44.+ per cent did not.

Some of the follow-up reports in the cases which recovered are interesting.

R. D., age 46, is reported five years later as follows: "He is better mentally and physically than I have ever known him to be. His wife has given birth to a baby which is perfect in every way."

About another patient, W. E., age 45, it is written:

As to his sickness it is a closed matter at home. He is supporting his children at college without family assistance. He and his wife are extremely successful socially in their town.

Of a third patient, W. W., age 38, his doctor writes:

Patient is in good shape, is working and is in as good condition as I have known him. You can consider him a cure.

Of the 38 cases all but four were treated by malaria: of the four, one was treated by the arsenicals and recovered.

OUTCOME FIVE YEARS AFTER ADMISSION.

	No. of cases.	Re-covered.	Im-proved.	Unim-proved.	Dead.	Lost.
Dementia præcox	116	12	25	66	10	3
Manic depressive	171	86	19	30	24	12
Paresis	38	13	8	5	12	..

Paranoid conditions	9	3	3	2	..	..
Unclassed	72	27	13	11	8	13
Psychopaths	8	..	4	2	1	1
Encephalitics, adult	8	1	1	2	2	2
Total	626	200	102	146	129	48

THE PSYCHONEUROSES.

Certainly 37 are best classified here although we have a prejudice that few uncomplicated psychoneurotics come to an organized mental hospital. Personal recollections are many of patients admitted as "psychoneurotics" who turned out to be schizophrenic. By the five year follow-up many such cases have been eliminated. Some were neurotic reactions to physical diseases and to external causes. The recovered were at work and without the symptoms for which they came.

Recovered	21	Unimproved	41
Improved	7	Died	3
		Lost	2

THE UNCLASSED.

Perhaps enough has been said about our efforts to keep other diagnoses exact by making this group large. Its group of "lost" is

the largest because many patients stayed a day or less in the hospital and no real contacts were made. Some seemed half-way between manic depressive and some other psychosis: in many the influence of some somatic diseases was doubtful. Five years did not clear these diagnoses.

Recovered	27	Unimproved	11
Improved	13	Died	8
Lost	13		

Summary and Conclusions.

Five year follow-up studies for all patients admitted consecutively in 1927 and 1928 to a large private hospital for mental diseases are presented.

Of 710 admissions 84 were inebriates, children with behavior disorders, epileptics or feeble-minded. These 84 are not reported, leaving 626.

For all 626 cases a one-page summary was made to give a picture of life-events.

For 626 consecutive cases the outcome after 5 years was:

Recovery	200	Unimprovement	146
Improvement	102	Death	129
Lost	48		

Deducting the 48 lost cases, of 578 consecutive cases followed, nearly 35 per cent recovered, 18 per cent improved, 25 per cent showed no improvement or retrograded, and 22 per cent died.

Of 116 cases of dementia præcox, 12 recovered and 25 improved to a greater or less extent.

The above figures furnish a base-line by which new therapy can be judged.

The use of one-page abstracts allows easy reference to the salient points of individual cases.

THE SOCIETY, THE INDIVIDUAL, AND HIS MENTAL DISORDERS.

By W. LLOYD WARNER, Ph. D.,
Associate Professor of Anthropology and Sociology, University of Chicago.

Part I.

This paper briefly states the thesis that there is a relation between many of our mental ailments and the social situations which exist in our kind of social system. In proof of this, an examination will be made of the general functions of a society, the individual's place in the social system, and, in particular, certain of the more critical social positions in our own society which, it is argued, contribute to maladjustment. A conceptual scheme which provides a logic for uniting the opposed dichotomous concepts of "the individual" and "the group" will be presented. This last corollary has been appended to the general statement to provide a framework for the collaboration, now almost absent, between the practitioners of the two scientific systems for the study of human behavior, and for the practical application of the findings of the sociologist to psychic therapy.

Ordinarily social behavior is seen from either of two points of view: the first considers the individual as an absolute unit and attempts to discover the meaning of social behavior in separate individuals; and the second sees the behavior of all individuals as a set of relationships bounded in space and time. The continuous interaction of the individuals with each other within the framework of these relationships is a group behavior usually called a society.

A society can be studied from at least two points of view. Certain social anthropologists and modern historians have examined it with the purpose of placing it in a time scale and making certain historical reconstructions. Others have looked at society as though the time aspect were not present and have attempted to see the mechanics of present-day society to determine if generalizations could be drawn to explain the forces which operate in this society. This paper will discuss society from this last approach to human be-

havior, and will look at the group and forget the dimension of time, although, of course, its importance is admitted.

How does the social researcher look at concrete human behavior in such a framework? He must constantly keep in mind who he is as an observer; the "objective" scientist is aware of his own prejudices. With this in mind, human behavior can be observed in three ways: (1) the observer can watch the actions of an individual or individuals; (2) he can record verbalizations; and (3) he can observe the concrete products of social behavior (technological objects). There is little else that he can do by way of collecting concrete facts for later inductions from which generalizations can be made that modern science would accept as valid. Out of this concrete material (physical behavior events and verbalizations collected) certain generalizations can be abstracted which will give us a scientific statement about the kind of group behavior studied.

Group behavior as seen in the present framework possesses a certain fixity in time. That is to say that although change occurs as the generations succeed each other, there is more of the old in the behavior of a given generation than there is of the new. In any given part of the social structure variation will always be found, but in any society which is functioning properly this variation is likely to be at a minimum. For example, in a family structure one sees certain relations between fathers and sons, mothers and sons, husbands and wives, and from these a general statement may be made out of this part of the structure studied which can be tested over generations of time to prove that the various individuals of the society act in this particular group situation with very little variation at a given moment or through the several generations.

Society does three very necessary and useful things. In the first place, no matter how complex the society, a hunting and gathering one at the stone-age level, or a steel and electrical one such as our own, it uses its technology as a means of adjusting itself to its natural environment. The technical behavior of a people relates it to the natural environment so that nature is no longer hostile and the food-gathering behavior is no longer purely that of animals. The technology socially organizes this behavior for man.

There is a second type of human adaptation which relates men together as social individuals. It formalizes relationships and limits the individual variation of each of these relationships. This kind of

adaptation ties human individuals into a general kind of behavior, so that in any given situation they will act in a similar manner. Our social organization not only relates us to each other but helps us to organize our technology to provide a division of labor to handle the various tools by which we change nature to give us our living. Our social organization is also a social mechanism by which we divide the goods we get from nature. If there is a class system such as we possess, the division of labor and of goods is of an unequal kind. On the other hand, if there is a purely democratic society, as are some of the primitive ones, there may be an equal division of goods and of labor among the individuals of the group.

Finally, there is another kind of adaptation which consists of the system, or systems, of beliefs or ideologies and sanctions; in other words, a symbolic level which serves to integrate the other two types of adaptation and integrate the group into a whole. Every society has a symbolic system or symbolic systems, and the symbolic systems of the several societies differ according to the kind of social organization and general behavior found in each group. There is a close relationship between the symbolic system and the organization of the society in which that system is found.

These three adaptive systems not only relate the individual to the total situation in which he must live, but they also exercise control over his actions in the group. The social organization controls his behavior so that he is bound by a set of relations to other individuals in his group. The symbolic system dominates the order of his thinking so that he cannot think outside the symbolic apparatus which the group provides. Variations and changes constantly occur, but the individual still thinks within the general framework of the symbolic system that the society gives him, even though that system may be a changing one. This symbolic system is a part of the general social life in which he participates.

The several types of social adaptation and control limit the variations of these variable individuals and integrate them into a unified group. Nevertheless, there is always a certain individual variation within the group membership. This individual group differentiation can only go to certain limits or the group itself will disintegrate. It is impossible, for example, for it to advance to such an extreme that individuals may have private symbolic systems or private social systems of their own. Only the insane and certain unaccepted artists

and inventors, after our society has exercised extreme sanctions, are allowed such privileges.

The symbolic systems that all societies have are on various levels of abstraction. As social scientists we can observe the physical expression of the social interaction that occurs between two people as they talk to each other while they make certain gestures and sounds. With but little generalization and at only a slightly more general level of abstraction, the relationship of the two individuals is seen as that of husband and wife. The larger group to which these two belong is the limited family. Abstracting still more generally we reach a point where the family is conceptualized not only as a symbol of human social life but as a religious symbol, and it becomes the Holy Family of scripture, and it is fitted into a still larger symbolic system of Christianity, the Cross, and the whole apparatus of our religious ideology. Our symbolic system consists of a series of levels of abstraction, and one must know with what level one is dealing if one is to understand the verbalizations of an informant.

The foregoing statements briefly describe the general kinds of situations found in all groups. Our own society is but one of the thousands found throughout the world which make similar adaptations.

PART II.

One of the great problems of collaboration between the specialists who deal with the sciences of the individual and those of the group is that their fundamental principles are quite different and usually in logical opposition. Whenever the representatives of the two points of view attempt to cooperate on a specific problem, it has always seemed impossible to relate the two conceptual schemes. This difficulty can be avoided by the use of the concepts of the "social personality" and "the individual." The social personality of the individual is the total social participation of that organic item in its particular part of the society. It is thus possible to diagram or chart the social area of the society and the individual's place in it.

A given individual occupies a particular place in the social space of a given society because, of a possible multitude of places he might be in, he participates in this one place, and therefore has a social

personality different from that of any one else, unless another organic individual occupies exactly the same social space which he does.

Let us for the purposes of this exposition simplify our problem and give the social space of our society but two dimensions: a vertical one and a horizontal one. The vertical is a hierarchical order in which people occupy higher and lower positions, and the horizontal represents a social differentiation of behavior at any given vertical level. The rectangle in Chart 1 represents the whole society; lines A_1, A_2, A_3, etc., represent the vertical dimensions of

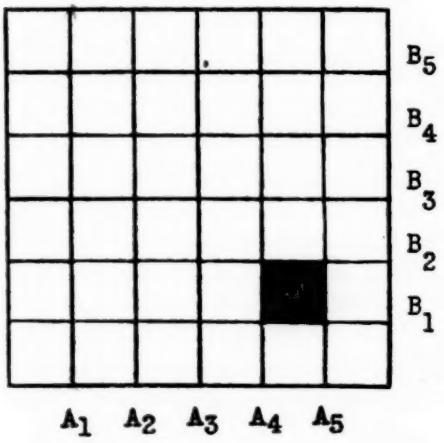

CHART 1.

the total society; and the lines B_1, B_2, B_3, etc., the horizontal. The top of the rectangle is the apex of the social hierarchy. The shaded portion represents the social place (or social personality of an individual) in which a given organic item in the group participates. Other individuals are like a particular individual because they may also participate in approximately the same place in the society that he does. One can say, for example, they are lower middle class persons who are of a certain family and of certain occupational groups.

The operations just described make use of both the individualistic and group points of view. They use the techniques and results of each general science of human behavior and yet do not discard the

leading ideas of either. Such a procedure does not produce two kinds of findings, the one psychological, the other sociological. On the contrary, the inner workings of the individual can be studied with the techniques of the psychologist and the same individual can then be examined within his social place, and his social place can be related to the larger society. More exact comparative analyses of individuals become possible. Individuals with like social personalities and like problems to be solved can be studied separately from individuals who occupy quite different parts of the social structure and who possess different social personalities.

A vital and fundamental question for mental theory and therapy can now be asked. How is an individual (this organic, psychic, social unit) using his part of the society? When we attempt to answer this question, we face the whole problem of mental hygiene, and when we know approximately what the question means, we can better solve the problems of mental therapy. How successfully is the individual utilizing for his purposes the society available to him? We are not asking how he compares with a hypothetical but non-existing normal person in the society, but we are trying to find out how his psychic equilibrium (or his success or failure) compares with other social personalities who by definition occupy similar places in the social system.

Furthermore, the complexity or simplicity of the personality will be determined by the kind of complexity or simplicity that exists in the society in which he lives, and in particular that part of it in which he participates. In other words, in a society such as ours there are certain parts more complex than others, and the personality of the individual will tend to be more complex or more simple according to that part of the society in which the individual participates. It seems important to remember that certain parts are by social function involved in greater conflict than others. Consequently individuals who have a social place in those parts of the social structure will be in greater conflict than those who are in other areas of the society.

The symbolic system of an individual will differ according to the part of the society that he occupies. For example, some of my colleagues and I have made a study of the social system of a county of Western Ireland. There are general class-groups, among them the Ascendancy or Protestant Irish; the Catholic Irish who make up

the vast middle class; and the small group at the bottom, Catholic in name, who must marry within their own group but who are scorned by the others and who are called the Tinkers. The Tinker group is nominally Catholic, but the symbols they use are only in part the symbols used by the rest of the Catholics. Furthermore, the religious symbols of the Protestant Ascendancy are different from those used by the other two. The individual Irishman's symbolic system will depend upon the kind of society in which he lives and that part of the given society which he occupies. This situation is one with which we deal at all times when we interview human beings.

The misuse of the symbols of the social organization can be divided into two general categories: the malfunctioning of the society itself and the faulty orientation of the individual in childhood. A person endowed with a normal physical body, organized so that it functions normally, in all likelihood will function properly in the general social environment. But even though he may have a normal physical endowment, there is still a very good chance that he will not be able to use properly the society in which he has to live, for the reason that either he may not have been oriented successfully to it in his earlier or later development, or parts of the society may not be functioning successfully and this particular person may be unfortunate enough to occupy a part of the society which is functioning badly. It still must be remembered that all parts of the society may be functioning properly but by their very success destroy many of the organic items who occupy particular social places. Durkheim was able to demonstrate that certain kinds of suicide (and mental disorders should be added) were due to the fact that society itself had partly disintegrated—that is to say in the life of an individual that part of the society which he occupied, disintegrated, and the individual who formerly had a satisfactory adjustment to the society could no longer adapt himself, even though he made what had once been the proper responses. Such an individual " feels like a fish out of water " and one course of action for him is suicide. However, suicide might be avoided by a psychosis or a neurosis.

Some of the situations in our society which are unbalanced and possibly disintegrate, and which may contribute to our mental disorders will be summarized:

We have a shifting technology. Our rapidly changing technical system is constantly making people re-form themselves into new groupings and adopt new thinking after they have learned how to live in a certain situation which was dictated in part by the former arrangement of the technology. One only has to observe economic changes which have been taking place in New England with the textile, shoe and other industries leaving, or examine changes in the South where these industries are settling. There is a constant demand on the individuals living in the two areas to make readjustments. Many are not able to do it; others find it extremely difficult. The subtle and varied changes create too great a strain on the psychic life of these individuals. We see in their behavior a disintegrating system to which they strive in vain to adjust themselves. Change continues in our social system, for as our technology shifts and our industrial revolution rapidly increases, the social organization must shift with it.

Our society no longer provides a well-ordered system for us to use. The web, one might say, is frayed and broken and the individual himself must pick and choose, that is, think his way through it. Such thought is related to some of the more characteristic types of mental ailments which we recognize in this society at the present time. As part of our society has been reforming with attendant breaks in the social organization, we have had a decided change in our symbolic systems. The old absolute symbols in which we had complete faith, which dominated us, and which controlled us as absolute ideas beyond which we could not think, have been disintegrating. As a consequence, there has been no place where an individual could say privately or publicly, "This is absolute and certain," without thinking again that after all there are other absolutes, since the people around him may have additional absolute systems which in part will contradict his own. An example of such a conflict of absolutes is the conventional fight between science and the church. The break-up of the one church into many varieties of Protestantism is another. The existence of separate small ideologies or creeds in small groups throughout the country is another. The city of Los Angeles is famous for them. There are thousands of people who come there from everywhere who bring scores of social traditions with them to a place whose social order was disturbed by the early inundations of populations and the social tradi-

tions which these people brought. Most of the inhabitants have no regular order which fits the need of the whole group. The farmers who lived a rural existence in Iowa and prayed to their God for rain to water their crops, and as such once had a workable social system, now find themselves in an urban environment where their old social system and prayers for rain are the antithesis of what their new situation demands. As a consequence we find thousands of little cults, none of which seems to be satisfactorily helping the individual solve his problems in relating himself to the world around him. One need not go as far as Los Angeles to find similar situations. One needs but look around him.

Another interesting phenomenon, very closely connected with this shift in our technology and with the disorder in our symbolic systems is the appearance of a great variety of ethnic traditions which make up the present life of our larger cities and small towns and rural areas. Here again are conflicting social organizations and conflicting symbols, which theoretically might ultimately result in complete breakdown of the society. For the individual the interaction of the several ethnic traditions forms a region of conflict in which he must think and not feel his way. He cannot depend upon his social logics (an ordered thinking and way of action provided by his society) to solve his problems for him. He must select and choose, and to do so at all times may be too heavy a burden on his psychic life. In our society we place a high premium on intelligent choice and action, but despite this we cannot be consciously selective in most of our acts, since to be mentally healthy, our society must provide an ordered way of thinking and acting for us.

Another social situation which has contributed greatly to some of the difficulties that are found in the mental life of many modern individuals is social mobility, that is to say, the going up and the coming down the social ladder in our class hierarchy. Many people move up rapidly, arrive at a certain place, and their upward progress is then stopped by pressure from above them: the individual's frustration often develops into neurosis. Other individuals have never been able to adjust themselves to any particular place in the shifting class world around them, and, as a consequence, they have difficulty in living effectively with other individuals. Personal insecurity because of class mobility is characteristic of American life and has provided at least the beginnings of many mental ailments.

In our southern states we have a caste society, the negro caste being subordinate and the white caste supraordinate. Within each of these castes there is a class situation. These caste and class elements are in conflict. The conflicting sentiments and feelings in the lives of the individuals who must live in that society are in part manifestations of the caste-class conflict.

Many of our social situations are in conflict, and most Europeans and Americans are in situations which make it very difficult for them to adjust themselves. The many stresses in our own social system create individual insecurities in which many people are unable to live adequate healthy existences. Some of them fail and these individuals find their way to the clinics and mental hospitals.

EXOGENOUS REACTION TYPES IN BRUCELLA INFECTION.*

(Undulant Fever.)

By PROF. B. N. SERAFIMOV, Leningrad.

Although the literature on brucellosis has been accumulating for many years comparatively few investigators have concerned themselves with the changes of the nervous system and particularly at its higher levels. However a knowledge of the psychic changes both in the initial stages of the brucella infection and in chronic protracted cases is of interest not only for the psychiatrist and the neurologist, but also for the general practitioner. Brucellosis has long ago left the limits of the hot climates and the corresponding geographical latitudes and it is a well known fact that cases of brucella infection may be encountered everywhere.

In the literature which I have been able to procure the reaction of the peripheral and vegetative nervous systems to brucella infection has been described as including pain in different parts of the body, especially headaches (of a paroxysmal character in the frontal and occipital regions), occasionally in the eye balls, neuralgia, polyneuritis (artalgia, ischialgia, myalgia, radiculitis), lumbo-ischialgia, neuritis of the optic nerve, its atrophy, muscular atrophy, temporary paralysis (paraplegia), paresis, hemiplegia, aphasia, meningismus, meningitis, meningo-encephalitis, encephalo-myelitis, transverse myelitis; more rarely symptoms of increased intra-cranial pressure with focal symptoms distantly resembling those of tumors of the brain, intention tremor, Parkinson's syndrome. Other symptoms are the falling out of the hair, brittleness of the nails, a tendency to perspire, constipation, increased pulse rate without a rise of the temperature, decreased blood pressure, disturbances of the menses, insomnia, increased irritability, general depression; also euphoria when there is no attack (Darkshevich) and sometimes "psychic disturbances of the type of psychoses in the period of convalescence" (Bresancon and Filibert). "It must also be re-

* From the Kasakh Medical Institute. Director V. V. Sikeev.

marked that the causal organism of brucella has been found in the cerebro-spinal fluid" (Roger) in which it has sometimes been possible to find positive Right's reactions. Besides, the cerebro-spinal fluid shows an increased pressure, pleocytosis, an increase of albumen and a decrease of the sugar and the chlorides contents.

With regard to the pathologo-anatomical changes of the vegetative and the central nervous systems in man during brucella infection, Jong considers this disease to be a non-specific, subacute local diffuse meningo-encephalitis with characteristic perivascular infiltration and a degeneration of the ganglia cells. Starker reports degeneration of the ganglia cells of the intervertebral ganglia, minute hæmorrhages in the cerebral cortex with ruptures of the blood vessels, local changes in the nerve fibres. Hansmann and Schenken have observed at a postmorten examination the picture of a chronic meningo-encephalitis with involvement of the vascular walls.

Our material consists of 25 cases of brucella infection, in all of which the reactions of Right and Burnet were positive.

In Table 1 the patients are distributed according to sex, age and duration of the disease.

TABLE 1.

	Age.				Duration of illness.				
Sex.	Up to 10.	20-30.	30-40.	Older than 40.	Up to 1 mo.	1-3 mo.	3-6 mo.	6-12 mo.	1-2 years.

Butchery workmen	1	..
Total	14	11

We see from the above tables that the greater number of patients were engaged in work near animals (zootechnics, dairy, cattle-shed and butchery workmen, etc.); it has not been possible to find any differences as regards sex. The greatest number of patients belongs to the young and middle ages. From Table 1 it will be seen that we had patients both in the initial stages of brucella infection and also chronic cases with relapsing clinical syndromes. Those stages were of great interest for the study of the effect of brucellosis upon the nervous system.

As a result of our observations it can be said that brucellosis even before the fever period, before the synovial and the osseo-articular systems are attacked, may produce the following complex of symptoms in the endocrine-vegetative and the central nervous systems: headache, pain in the eye balls, decreased working capacity, disinclination to do work not connected with the patients' professional duties, marked weariness, a peculiar absent-mindedness, irritability, disturbances of sleep, a morbid reaction to high and low temperatures of the air, sometimes hyperacusis and frequent micturition. These symptoms may induce the patient to seek medical assistance and most frequently the physician does not suspect brucellosis; he diagnoses "neurasthenia," "asthenia," "overwork," treats the patients accordingly and sometimes sends them to a sanatorium whence they soon return with the diagnosis "malaria (?)" "typhoid (?)" or "chronic rheumatism," as was the case with some of our patients. This "neurasthenic" period may last from one to several weeks. After that and sometimes without it appears the complex of depressive symptoms: dejection, anguish, constipation. The patients expressed their state in the following terms: "I am in agony"; "it is, as if I had lost something"; "how tiresome"; "I am bored"; "I cannot find a place for myself"; "I am thinking of suicide"; "I have no interest in life." Much more rarely this state is interrupted, as was the case with two of our patients, by motor restlessness with attempts at suicide. It is interesting to note that this depressive background was observed in our patients independently of their age; we had at the same time under observation a mother aged 52 and her daughter of 8 years with absolutely the same complaints of dejection and weariness.

From the point of view of the endocrine-vegetative system more specifically I have been able to observe the following symptoms: a marked increase in muscular excitability, intense contraction of the muscle fibres when tapping the cheek bone (pars orbitalis et palpebralis, m. orbicularis oculi) and a proboscis-like protrusion of the lips; dermography was increased in all cases, but the picture varied greatly from the red aspect to the pylomotor variety; in some cases there was a positive cilio-spinal reflex; rarely Chvostek's sign has been positive. Especially interesting were the results obtained both in protracted and in acute cases of brucellosis during the investigation of Ashner's sign; the latter was observed while pressing upon the eye balls. It appeared that in most cases there was neither an increase nor a decrease of the pulse rate; only rarely was there a change of 2-4 beats, while there were no such responses to other signs, such as Erben or Martinet. This singular "neurotonic" character of a changed Ashner's sign was more constant than the changes of other reflexes of the vegetative nervous system. Such disturbances of that system are probably due to profound changes of humoral and toxic origin.

In the tendon reflexes, we have had more cases of diminished than of exaggerated excitability (in one case there was a complete loss of the knee jerks and the Achilles reflex); changes of the pupillary response were observed only in 2-3 cases of chronic brucellosis, *i. e.*, the pupils were contracted and in one case there was a deformed pupil and the light reflex was abolished. Disturbances of the skin sensibility were found when nerve trunks or their branches were involved in the process. With some patients we could observe hyperacusia, and a singular fear or timidity when they were in a high place; there had been no such symptoms before their illness. The latter phenomena may be explained by changes in the vestibular apparatus under the influence of infection.

Memory disturbances were mostly limited to the processes of reproduction and retention; thus for instance these patients, when shown 5-7 pictures of common objects, could retain in their memory one or two of the pictures. It would be difficult to explain these memory defects as being due only to "post-infection dysthymic asthenia," because positive Right's and Burnet's reactions indicated that the infectious process was still continuing; the same could

be inferred from the fact that treatment of the brucellosis improved the memory of the patients.

To illustrate these conditions a short description of some of our cases is given.

1. Tr-na, V. M., female, age 24, zootechnic; no evidence of hereditary taint; normal growth and development; successful studies at school and at a technical institution; was graduated in 1935 and sent to Kasakhstan for practical work; within the last months she had to work much, was underfed and could not keep to regular meals. Once owing to difficulties with the traffic she had to walk about 10 kilometres; when she came to a farm she drank a glass of unboiled milk and in a few days began to suffer from gradually developing fatigability, general weakness, headaches, pain in the eye balls, weak memory ("I have read a line 10 times and I cannot remember anything"; "when I get up I cannot remember what I must do"). In about a month the patient became very depressed and once even made an attempt at suicide, but it failed because "the string tore"; about this time there was a rise in her temperature, pain appeared in her articulations, especially in the knees and the hip joints; her state became worse, her temperature went up to 39.5° C. sometimes.

This acute period lasted for about four months; the patient all that time was kept at the town hospital of Alma-Ata with the diagnosis "brucellosis." Right's and Burnet's reactions were markedly positive. At the beginning of August the patient was discharged in a good state and went back to her work.

On August 28 the patient was directed to me for a consultation. She complained of periodical insomnia, bad appetite, irritability, frequent crying, dejection, an increased sensibility to ordinary acustic stimuli, fear of being in high places, frequent feeling of being cold, a change of the menses (longer duration 3-5 days), weak memory; the latter the patient noticed when reading papers or books: "I read much, but if you ask me in half an hour, I cannot remember anything"; "my memory is like a sieve, it does not retain anything." When shown five objects, she could remember only two. In her disposition there predominated general dejection and weariness, but there were no thoughts of suicide; besides, there was a tendency to shun other people's society and the patient considered her life to be a useless burden. No other psychic deficiencies could be observed.

Physical examination: asthenic build with deficient nutrition; hypomimia; slight asymmetry in the innervation of the right facial nerve; decreased blood pressure (100/60); red, stable dermography, increased mechanical muscular excitability, contraction of the m. orbicularis oculi when either cheek bone is tapped, Ashner's sign 64-60-64, Martinet's formula 70/64. There was an increased tendency to perspire, a dryness of the tongue, tremor of the outstretched fingers, tongue and closed eye lids, equally dilated pupils with vivid reaction to light and convergence, low knee jerks; the reflexes of the mucous membranes were normal; so was the skin sensibility. The heart was dilated to the left, its beats were dull; there was slight flatulency; percussion of the

spleen showed its upper limit to be at the eighth rib; the region of the liver was tender. Active and passive flexion of the left hip joint and knee was rather painful. Right's and Burnet's reactions were positive.

In this case it is interesting to note that the beginning of the illness was connected with the consumption of unboiled milk at a time of exhaustion and tiredness; it is also interesting that of the group of people who had been with her and had also taken the same milk only our patient Tr-na caught the infection of brucellosis; this circumstance makes it probable that there exists a certain individual predisposition for brucellosis. In our patient at the beginning of the illness a neurasthenic period was observed which was followed by depression with an attempt at suicide; it has been ascertained that our patient did not belong to the type of "depressive psychopaths" as described by Schneider and had never before evidenced symptoms of constitutional depression. Thus we may draw the conclusion that in this patient there developed an exogenous reaction which may be classified among the exogenous reaction types of Bonhoeffer.

2. Ro-ov, male, age 52, Russian, born in Kasakhstan, medical dresser, married; heredity taints: father alcoholic and stammerer; patient also stammers since childhood; several relatives have died of cancer. Patient was lively and active as a child and was easily agitated; his school work was satisfactory, but he was hampered by his stammering. After school he entered the medical dressers classes and then did his military service; he took part in the World War and the civil war; has had typhoid, paratyphoid and malaria. During the last years has been working in the country as a dresser, worked very hard, had to drive about his district very often, could not keep to regular meals, often drank unboiled milk, though warned by the veterinary surgeon that the cattle of the district were infected with brucellosis.

The patient describes in the following way the beginning of his illness. At the beginning of April, 1936, he began to suffer from headaches, progressing fatigability, general weakness, irritability, a weakening of the memory, pain in the spine, pain in the articulations especially in the lower extremities; the temperature began to rise irregularly, there was constipation, accompanied by a disagreeable sensation in the region of the epigastrium; there appeared a tenderness in the regions of the liver and spleen.

The patient was sent from his district infirmary to the city hospital at Alma-Ata where Right's and Burnet's reactions gave positive responses. At the beginning of October the patient's physical state improved considerably: the temperature fell, the pain in the joints decreased considerably, the bowels moved more regularly, but in his psychic sphere there appeared a depression: dejection, thoughts of suicide, a marked weakening of the memory, insomnia, dryness of the mouth.

On October 11 the patient was examined by me at the clinical therapeutical department of the town hospital of Alma-Ata. Somatic findings: athletic build, nutrition markedly impaired; spleen and liver somewhat enlarged but not tender; epididymitis; in the lungs some dry and wet râles. The limits of heart were extended, its beats dull; the pulse 90, labile; there was a slight cyanotic tint of the lips; Ashner's sign 76-76-80; Martinet's sign —90/76; blood pressure 90/50; an increased mechanical muscular excitability; contraction of the m. orbicularis oculi when the cheek bones were tapped; red dermography with a white reactive stripe; a dry tongue; tremor of the fingers and the upper lids; lively tendon reflexes; the pupils were irregular in shape and reacted insufficiently to light; otherwise their reactions were normal; there was frequent micturition; the patient stammered. Psychical status: depression but with no symptoms of an inhibitive state; the patient was sullen and dejected, spoke of suicide, but did not accuse himself of anything, *e. g.*, "everything is horrid, it is better to die"; "I ought to take several powders at once and everything would be finished." There was a tendency to remain alone; the memory was considerably impaired; thus of six objects that were shown he remembered only three; his sense of hearing was intensified; all these symptoms became worse towards evening. I have not been able to observe any other irregularities in the patient's psychical status. This is another case in which a depressive state developed in a brucella patient.

3. S. G-ov, male, age 32, Russian, born in Baku, single, employee. Family history: his father died of apoplexy; he had suffered from phobias and fixed ideas, used to drink; his mother was "sly" and died of a disease of the heart; there were 12 children, the majority of whom had died in infancy; our patient was the ninth child; he had great difficulties in his childhood, was not taught to read and write; from his 11th year he began to work, at first helping porters and then the peasants. In 1919 he enlisted in the Red Army as a volunteer where he learned how to read and write; in 1930 he entered a technical school which however he did not finish and was sent to work to Kasakhstan where he spent three and one-half years. He had never suffered from marked changes in his temper. During that period he had had typhoid, malaria and nephritis. In 1935 in the region where he worked there began a disease of the cattle and pigs; our patient took part in coping with that disease, but did not take care of himself; he drank unboiled milk and often used to eat sheep's cheese. In December, 1935, after having been ill with tonsillitis he began to suffer from fatigue, lack of self confidence, irritability, headaches, weak memory, restlessness at night. That state lasted about two months and then together with increased irritability, irascibility and marked fatigability there appeared a pain in his bones, in the calves of his legs and in his right knee, while his temperature more rarely rose to 38° C. What greatly upset the patient and caused him to seek medical assistance, was a marked weakening of the memory concerning current events, which had led to several disagreeable conflicts in the service. His physician having suspected brucellosis sent him to the hospital for the purpose of having the specific reactions performed (Right, Burnet) which gave positive responses. On Octo-

ber 8 the patient was directed to me for a consultation. Somatic status: asthenic build, medium nutrition, lungs normal, heart slightly dilated to the left with dull beats, pulse 78, labile, Ashner's sign 74-72-72, Martinet's sign 78-74, pupils normal, marked red dermography, increased mechanical muscular excitability, contraction of the m. orbicularis oculi when the cheek bones were tapped; decreased tendon reflexes; tenderness of the legs when pressed; liver not enlarged and not painful; spleen enlarged but not tender; frequent micturition. Psychic state: low spirited but no stupor; thoughts of suicide but none of self accusation or self abasement; complaints of a depressive incomprehensible anguish, heaviness in the head and insomnia; that depression arises "out of the depths" of the patient, is "incomprehensible," and "is in no way connected with the patient's surroundings." The morbid state was very stable and generally became worse towards evening. Besides there were disturbances of the patient's memory concerning the latest and current events; however there were no false reminiscences and no tendency to confabulation. Of seven objects which were produced the patient could remember only three. It was interesting to note that the patient's sense of hearing was more acute; he himself considered that to be due to his morbid state. There were no other pathological changes in his psychical state. This is undoubtedly a depressive state in a patient with brucellosis.

THE CARE OF EXTRAMURAL PATIENTS WITH MAJOR CONVULSIONS.*

By DAVID C. WILSON, M. D.,
University of Virginia.

In the management of patients with convulsions in an out-patient department the classification is very simple. In those cases in which the cause is known the patient is designated by the cause, namely, a case of syphilis with convulsions, a case of brain tumor with convulsions, while the remainder are grouped as cases with convulsions in whom the cause is not known. The former, with known etiology, can be referred as soon as classified to the appropriate department for treatment, while the latter become the property of the neuropsychiatric section until more exhaustive study indicates need for further consultation, or by proper handling the case ceases to be a problem. The study presented here concerns only those cases initially classified as having convulsions of unknown etiology and referred to the neuropsychiatric clinic as such.

The value of the study is that the close follow-up allows an estimation to be made of the different methods of managing such patients who are often considered hopeless or in need of institutional care.

Since 1929 at the University Hospital at the University of Virginia a determined effort has been made to keep in contact with the patients suffering from convulsive seizures. By means of repeated returns to the out-patient department and by follow-up letters at stated intervals the career of each individual has been followed in so far as it was possible. The experiences of this group were reported in 1932 and again in 1934, when the effect of different forms of therapy was considered. Patients with convulsions of a recurrent and chronic nature who have entered this hospital for the first time over that period, average in number 50 a year, making a gross number of 350 patients. Of these, all of which

* Read at the ninety-second annual meeting of The American Psychiatric Association, St. Louis, Mo., May 4-8, 1936.

are worthy of the diagnosis of "epilepsy," 231 have been followed in some form. As it is felt that no estimate can be made of any form of therapy which has not been in existence for at least a year, only 126 cases are considered proper for this report. We report here, therefore, 126 patients from the wards and out-patient department of a general hospital that have been followed in the neuropsychiatric clinic from one to five years.

The object of therapy throughout has been to use every known method of diagnosis and treatment in order to maintain the patient in the community so as to enable him as near as possible to live a useful and happy life. The attitude has been assumed that the convulsion was always a matter of the whole personality and that any form of success in therapy must depend on noting carefully the effect of the patient on the environment and the reaction of

TABLE 1.

the environment on him. Diagnosis is always important, but it was felt that in a great number of persons the cause would never be known and if known, could never be removed, so that adjustment to a life with convulsions was imperative, and should be the object of therapy.

Up until the spring of 1935, 13 of the 126 patients had died; 16 had been forced into institutions. Of the 16, four are now diagnosed "dementia præcox" and two of these, since their psychosis has developed, have had no convulsions. Ninety-seven of the group are at large in the community, the majority in their own homes with their families. Seventy-three of the 97 are able to carry on their lives and to take a place of some value in the lives of others, while 24 are so handicapped that they are a burden and cause special situation adjustments. Seventy-three adjusted epileptics are very few it is true, yet the study of why they are adjusted gives a panorama of the therapy of major convulsive disorders.

Two cases were relieved by surgical removal of neoplasms. A small number, yet one which indicates the value of surgical intervention in relation to the whole field of epilepsy. Extirpation of convolutions and removal of tumors are worthy contributions, but are overemphasized perhaps by their spectacular nature when the whole field of convulsive disorders is considered. Three cases of major convulsions responded to psychotherapy; one case had extensive analysis, while the other two responded to the management of intolerable domestic situations. Here the relative importance of pure psychogenic major convulsions is illustrated. Perhaps we should expect four per cent (4%) of all seizures to be psychogenic. Three cases have been well since encephalography. Two of these showed a normal encephalogram and one an arachnoiditis. In five

cases hypoglycemia has been thought to be a factor. Our experience with this condition has been very interesting. Five-hour glucose tolerance tests have been conducted on all cases in which the history made hypoglycemia a possible cause and frequently the blood-sugar findings have been low at one period during the test, but in no case have we been able to produce a convulsion, or more in than a few of the patients, premonitory symptoms. Prolonged starvation has been tried with like results. Certainly, frequent feedings have helped some patients, but we cannot help but feel that hypoglycemia as a cause of major convulsions is rare.

Two cases of pyknolepsy have improved with puberty, while two other cases, both males, have presented an interesting picture. Both were in late adolescence when first observed. They were intellectually well developed, but emotionally greatly retarded. They were hyperactive and very unstable, but as the years have gone on

they have rapidly matured and as their emotional age has reached their chronological level the convulsions have ceased. Perhaps this is another type of pyknolepsy.

The remaining 43 cases are now on phenobarbital. An effort is made to adjust this drug to their individual needs. It is found that according to the strains they undergo, as well as their convulsive tendency, this drug can be varied with very satisfactory results. Dehydration is used only in combination with phenobarbital. Our experience with the dehydration regimen of Fay has been disappointing. The main difficulty is the poor cooperation of the patient when not under constant supervision. Yet, even in those cases where the total fluid intake was kept in the neighborhood of 400 cc. during an extensive period, spells would still occur until it was felt that the procedure was not worth the suffering it caused nor the difficulties arising from the program. On the other hand, in those cases which showed signs of impairment of the spinal fluid pathways in the encephalogram—either the so-called cortical atrophy or archnoiditis—the restriction of fluid intake to less than 1000 cc. daily seems to have allowed the use of smaller amounts of phenobarbital. The experience with the ketogenic diet has been very similar. This procedure is still used in the treatment of all children and most of the young adults who have convulsions of unknown origin. Each time the regimen had been continued for five to six months, then has failed to help or, at least, to help sufficiently to make it worth while to continue the high fat schedule, so the diet has been dropped and the patient with great rejoicing has returned to phenobarbital and carbohydrates. The ketogenic diet is easier to control than dehydration because of the urinary check and because it is not so hard on the patient; yet, in many cases, the condition of ketosis seems to have had very little effect on the number or severity of the spells.

Seventy-six cases had encephalograms. Twenty-six showed cortical atrophy; ten showed arachnoiditis; five showed arachnoiditis with ventricular enlargement and five showed distortion of the ventricles. In other words, 46 out of 76 showed some abnormality of the spinal fluid pathway, while 30 air injections gave a normal picture. It is still felt that the encephalogram is a necessary part of a complete study when no definite cause is found without its use. This form of study helps in prognosis and is of aid in therapy, as

has been mentioned above. Yet, it is felt that here again we are using a technique that we may later discard. The value obtained from the study may be considered hardly worth the trouble and suffering caused by the procedure. If all neurological studies are negative and there are no focal symptoms during the attack, it is rare that the encephalogram adds any vital information.

Bromide when combined with regular estimation of the concentration of the drug in the blood serum has proved fairly satisfactory, but as a rule it causes an uncomfortable drowsiness and sluggishness not found when phenobarbital is employed properly. At the present time the former drug is used only when the latter fails and then usually in conjunction with it. Bromide is of more value in the control of minor attacks so it is used when petit mal is present.

The most important consideration, after all, in the care of extramural persons with this affliction, has been the handling of the environment. Since we admitted from the first that our objective was not cure necessarily, but the optimum adjustment of a patient with convulsions, each case has been a social problem from the start. A great deal of our success has arisen from the fact that our community is a rural one, as certainly the complexity and mechanization of urban life increases the difficulty of life and above all the obtaining of employment. Mill work or factory work especially where compensation laws exist are very difficult places for patients with convulsions to remain employed. Indeed, the only successes we have had have been with patients so valuable that their handicaps were overlooked. Positions for road work and general labor can usually be obtained and maintained if special efforts are made to explain the situation to the direct employer. Here again the difficulty is the compensation law, but individual attention can often solve such problems.

The maintenance of children with convulsions in the schools is also hard to manage and in most instances special tutors or teaching at home is necessary, although it is surprising how much a sympathetic principal can do to control the attitude of the teachers and pupils toward the patient. Certainly a normal life in a normal environment should be the ideal and through investigation and effort a great deal can be done toward this objective. This ideal is important because extramural patients show less deterioration

than those in institutions. This is what one would expect as there is nothing characteristic about epileptic deterioration, depending as it does, on the individual's ability to meet his situation, just as it does in any other personality disorder and varying as it does, according to the type of personality involved. Therefore, the maintenance of a normal home life, normal employment and recreation is of greatest importance. The care of the extramural case then must invade the home, must call for constant contact and a mutual understanding very similar to that of the physician in the institution, but with the difference that the patient is in competition with normal individuals, so needs greater help. The socialization—the adjustment in the community—is the largest part of the extramural care.

To *summarize* then the deductions arrived at from following a group of persons living in a community while suffering from convulsive disorders have been presented and the value of different forms of therapy discussed. There are still many problems to be solved, but certainly when the convulsion is considered as a reaction of the individual in whole or in part, thus allowing one to bring every form of influence to bear on the amelioration of the problem, the study is more interesting and the outlook more optimistic. This study shows that in this group of persons commonly known as "ideopathic epileptics," but here designated as individuals with *convulsions of unknown origin*, much can be done. A large percentage have been able to live useful lives in the community. Some have apparently been cured, while others have outgrown their attacks. Also, although diligently employed, the ketogenic diet and the dehydration program have failed to be of lasting value, while disturbed carbohydrate metabolism has rarely been demonstrated and has never been proved to be a cause of convulsions. Finally, the proper management of the phenobarbital dosage and above all, the proper social adjustment of the patient has offered more than other forms of treatment.

DISCUSSION.

DR. WILLIAM L. NELSON (St. Louis, Mo.).—We here in St. Louis who have been working more definitely with special problems in behavior probably have had a little more favorable experience than Dr. Wilson in getting an acceptance of these individuals by our boards of education and their lodgment in the regular schools. I would like, if I may, to differ from Dr. Wilson as to

the advisability of training individuals of this sort by private tutorage. Thinking of personality as a reality interchange between the individual and his environment, I can't conceive of a narrow training of the epileptic in terms of vocational preparation under the type of training that is involved in tutorage; we need competition and coordinated and cooperative activity for him. Therefore, it is our task, I think, to persuade schools to accept these individuals, except during the time of a seizure. It is rather an easy thing for us here to get children accepted in the regular classes, and it is surprising what one can do in the schoolroom with both teacher and pupils in terms of their sympathetic response to a child with convulsions. I have seen a few of them in our schools and have seen the reaction of some of the pupils, and the pupils' reaction depends largely on the conditioning they get from their teacher; the school teacher, therefore, has her opportunity also in the general plan of care of children suffering from epilepsy.

DR. G. KIRBY COLLIER (Rochester, N. Y.).—It is very pleasing indeed to hear the optimistic note from Dr Wilson. Some years ago when this Section was first established, it was felt that it was wise to do away with the word "epilepsy." If there is any one word in the English language which spells horror to the layman, it is the word epilepsy. Personally, I make it a point when a patient is referred to me, whether it is an adult or a child, that the word "epilepsy" shall not be used at any time in discussing the symptom picture with the patient or in the family group. I think we all recognize so-called epilepsy, convulsive disease, as I like to call it at the moment, as a many-faceted disease; and if we are going to accomplish anything at all, it is only by a study of the whole personality as well as the environment in which the patient lives.

I hardly think it is wise to go into the medicinal therapy, but if we would pay a little less attention to the one symptom of convulsive disease, the convulsive attack, we would get along much better with our patients. We should study the individual as a whole, instead of merely considering and keeping a complete record of these attacks; that is important of course, but the whole life picture of the patient is far more important than any record of the individual attacks.

The last speaker referred to the school child. I fully agree with him that the place for the so-called convulsive child, with only the occasional symptom, is in the school. I have been associated with one of our large school systems for a number of years and it has always been my procedure to keep these children in school by the aid of a teacher, the home room teacher and all of those having contact with the so-called epileptic child, having the visiting teacher look into the home situation as often as possible and the child being seen in clinic as often as possible. A great many of these children can be kept in school and an adjustment brought about.

I fully agree with Dr. Wilson in what he has to say regarding the ketogenic diet. Personally, I have seen no results in the use of the ketogenic diet. I have seen results, however, in dehydration. I feel that we shall see better

results as we understand dehydration better. I think that we are forcing dehydration too far, and as we go into the chemistry more and more, we are striking a happy medium and finding a dehydration level which is followed by considerable improvement.

Dr. William N. Hughes (Providence, R. I.).—I should like to refer to the petit mal type of seizure in children. I received a great deal of help in the last few months from Dr. Wm. Lennox of Boston in distinguishing between the so-called hysterical type of petit mal and the organic type. He has done electro-encephalograms on certain borderline cases by means of which definite diagnoses have been made. I disagree as heartily as I can with Dr. Wilson in regard to the use of the ketogenic diet. I have got extremely good results with the ketogenic diet. In children under 15, with 25 or 30 seizures a day, when they are put on a carefully weighed ketogenic diet and follow it, the seizures unquestionably diminish, sometimes to none a day and at most to one or two or three. If these cases are treated before they are 15, Dr. Lennox hopes, and I hope, that the freedom from epileptic attacks may carry over into adult life.

In treating certain of these children with the ketogenic diet, children with pale, pasty faces, perhaps with a few pimples, very often develop red cheeks and the temper improves to a great extent. That is one of the remarkable things in regard to the diet. You give a child a high fat diet which is a very difficult diet to take and if you add to it adequate calcium, the complexion usually improves greatly, and the girls appreciate that a great deal.

Dr. T. B. Bass (Abilene, Texas).—Mr. Chairman, the treatment of epilepsy is largely an individual business based on the personality of each patient. The ketogenic diet, I have found, has been extremely difficult to carry out. It is hard to get the patient or their families to carry it out.

I should like to report one unusual case of dehydration. This patient was a druggist, a nervous kind of a fellow who occasionally had spells, but not very many. When he would wait on a customer, he would go back and take a drink of water. He soon developed the habit of drinking water every few minutes, he drank lots of water. His fits increased and his condition became such that he couldn't attend to business and he was sent to our institution. We noticed his desire for water, and we shut the water off and put him on dehydration. After a year, we were able to control his drinking water and his convulsions almost ceased. Now he has been out for about a year. He doesn't drink water except when absolutely necessary and he gets along pretty well and has very few attacks.

Dr. David C. Wilson (University, Va.).—I don't believe that special tutors are a good idea, as Dr. Nelson seemed to think. Certainly we have had a great deal of difficulty in keeping convulsive children in the schools. With regard to bromide and phenobarbital, the great point is to study your individual case; you have to follow them very carefully and you have to have a

rather intelligent mother or intelligent person who will help you in the control of your drug. I think this giving of blanket drugs and letting the person take three grains a day or six grains a day and letting it go at that is improper.

I was very glad to hear Dr. Hughes speak of the ketogenic diet. I am sure there are others here that have used it and have had success also. I understand that they were private institutional cases, that he had such good results with and not clinic patients.

I am quite disappointed that no one took up the glycosuria point of view.

One thing we have noticed with cases in which we have followed the five-hour curve; it sometimes drops to 45 or 50, and yet you won't have symptoms.

We feel that perhaps it is a sudden drop in the glucose in the blood that is the factor, but this is a matter for further observation.

A REVIEW OF ONE HUNDRED AND FORTY-FOUR CASES OF AFFECTIVE DISORDERS—AFTER SEVEN YEARS.*

By LESLIE B. HOHMAN, Baltimore, Md.,
Associate in Psychiatry, Henry Phipps Psychiatric Clinic, Johns Hopkins Hospital.

At a time when psychiatry is so occupied with disputes about methods of psychotherapy it seemed that it might be valuable to look at psychiatric material from the objective point of view of symptomatology, course and outcome. It is important to know what disease will do of its own accord. I wonder if the review of cases after decently long periods of time would not bring many surprises to everybody—both as prognosticators and therapeutists.

From the time of my introduction to psychiatry in 1914 it seemed to me that the Kraepelinian doctrines have kept an almost strangle hold on psychiatric thinking. Either we have followed slavishly the manic-depressive doctrine and forcibly distorted cases to fit the mold; or, we have rejected the manic-depressive concept and have been tempted to throw overboard all of the virtue of the idea of symptomatology, course and outcome. With the rejection we have reached for (a) *complete* psychogenic or (b) brain disease explanation.

To try to test the wisdom of these conflicting positions, I decided to study a group of cases which I had seen in my private practice in the year of 1929. I selected 144 cases which represented all the cases of *affective psychoses* † which I had seen in that year. These cases for the most part were referred to me by prominent internists

* Read at the twenty-fourth anniversary of the Henry Phipps Psychiatric Clinic, April 16, 1937.

† By affective psychosis I mean a mental illness which, generally speaking, is characterized by a pervasive mood (usually depression or elation or a mixture of the two; but the pervasive mood can be fear or anxiety or bewilderment or anger); with a tendency to loss or increase of interest, slowness or speed in thinking and talking, disturbance in appetites and sleep, diurnal variation in symptoms; a tendency to develop somatic complaints, and ideas of self-depreciation and accusation or self-elevation. I do not distinguish between neurotic and psychotic affective disorders except quantitatively. Qualitatively I do not accept the distinction.

who were conducting intensive diagnostic studies on these patients. My psychiatric opinions formed a part of this general medical survey. The series is essentially an extramural group of patients and involves a type of case which does not therefore ordinarily come into the hands of the psychiatrist. The series probably includes more physical illness than a similar group selected from a mental hospital service. There were more males than females (86 males, 58 females), but this is due to the fact that there are in Baltimore women psychiatric consultants who are more likely to be asked to see our women patients.

I selected the year 1929 because it antedated the financial depression and because it gave a seven-year period for the follow-up.*

In my written opinions in this series of cases I gave diagnoses which were essentially descriptive—expressing whether (1) I thought the mood disturbance predominated in the picture of the illness; (2) the main presenting symptomatology was—hypochondriasis, fear, panicky states, anxiety, delusional or hallucinatory material, invalidism, agitation, puzzling, confusion, unreality feelings, paranoid attitudes, etc.; (3) organic brain damage in the form of memory or judgment impairment, or focal brain disease signs were present. The diagnostic description usually included some etiological opinion such as "reactive to psychologic causes"; "constitutional," or "secondary to physical disease." I also gave a prognostication—good, guardedly good or guardedly poor, and poor.

The factors which made me give a guarded prognosis were in part as follows:

1. Evidence that the affective component might be less pervading than it seemed. One therefore had to weight the prognosis on the possibility that depression was only accompanying a chronic psychoneurotic or invalidism state.
2. Prolongation of illness beyond three years.
3. The presence of organic brain disease.

* A letter was sent to each patient asking if he had recovered from the nervous illness which he had in 1929; if he had recovered had he had any recurrence of the illness?, and each patient was given the opportunity for a longer comment if he chose.

Each patient was sent registered mail if he failed to answer the first two letters of inquiry. Of the 144 cases we have had responses from 122. (We have some information on a few of the patients who did not respond.)

4. The age of the patient. Cases beyond 60 were thought to have less good outlook.

5. The presence of paranoid features.*

6. The presence of distorted hypochondriasis.

7. The tendency to alternate between elation and depression without intermissions of normality.

This type of descriptive diagnosis involves the making of many quasi-diagnostic categories, many of which I am now prepared to abandon after studying this material. After this review, I feel that we can make only this statement; where mood disturbance is prominent and pervasive, patients tend to recover irrespective of other symptomatology, including brain disease, duration of illness, precipitating cause or age. To my surprise I found that the factors enumerated as making the prognosis doubtful are much less decisive or critical than I would have suspected. For example, when one reexamines the records of the cases over 60 years of age one finds the following facts; of 21 cases 5 must be excluded (2 are without follow-up information and 3 died surgical deaths within a few months); of the 16 available cases—10 recovered completely, 2 improved markedly, and 4 failed to recover. Now one-half of the cases showed memory defects which were equally distributed between recovery and non-recovery.

As to duration of illness the following facts are available. Of 122 cases we have 85 cases of recovery (22 of the series are excluded because of no follow-ups). The durations of the illnesses ranged from 3 months to 11 years. 33 of the 85 recovered within one year; 23 of the 85 within 2 years; 10 of the 85 recovered in the 3d year; 5 in the 5th, 4 in the 6th, and 3 in the 7th and one each in the 8th, 9th, 10th and 11th years. The number of recoveries after 3 years (19 out of 85) was to me very striking.

It appears to me from the study of this group of cases that the tendency to run a self-limited course is strongest in the absence of the factors which I have enumerated above as leading to guarding of prognosis. For example, in 82 cases when I predicted recovery without question, 69 of the cases recovered completely and only

* Obviously other schizophrenic features would be regarded as having unfavorable prognostic significance but the series did not include any cases with schizophrenic admixtures.

7 failed to recover (6 cases must be eliminated because of death, suicide or development of profound brain changes). On the other hand in the group of 40 cases in which the prognosis was guarded, 13 recovered, 6 improved and 18 failed to recover (2 excluded because of suicide). Thus one can say that in cases with clear-cut affect nine-tenths recovered; where there were untoward signs less than one-half recovered. In reviewing the cases that failed to recover no single type of untoward sign or symptom seems to have operated critically. Patients recovered, and did not recover, with and without:—cerebral arteriosclerosis, continuously alternating elation and depression, continuing situational difficulties, with advanced age, with background of suspected chronic psychoneurotic or chronic invalidism, and with paranoid attitudes.

I was further impressed with the fact that of the 133 cases of affective disorders there were only 11 cases which had, or had had elation as part of the illness. This confirms an opinion which I have long held that the concept of manic-depressive insanity cannot be reconciled with the overwhelming preponderance of depressive cases. If only one-thirteenth of the cases had elation at any time, I cannot believe that we are looking at the same illness in all affective disorders—even discounting the fact that mild elation would tend to escape medical supervision. Of course elation of severer degree does require prompt hospitalization.

As against my experience, in a report to Dr. Adolf Meyer by the statistician of the New York State Hospital Commission for the ten-year period between 1910 to 1919, there were reported over 8000 cases of manic-depressive admissions and 67 per cent of them were tabulated as manic, mixed, or circular, and only 33 per cent depressive.

It is difficult for me to reconcile this discrepancy unless it be that manic excitements almost invariably require hospitalization and commitment. I say commitment also because my original impression of the large preponderance of depressions over elations was gained from the material seen at the Phipps Psychiatric Clinic, a hospital which does not accept committed cases. I made a further check, through the staff of the Sheppard & Enoch Pratt Hospital, a private hospital, which receives commitments, and their material shows a great preponderance of depressions over elations—their guess being 4 or 5 to 1.

Although the number of cases is too small to make any definite statement it is my impression that a significant part of alternating cases without intermissions of normality tend not to recover. Four of seven cases failed to recover.

I said above that I was prepared to abandon many of the descriptive categories which were used because I cannot see from my group of cases that they contribute any diagnostic, therapeutic or prognostic value. Some so-called simple depressions did not recover; all patients with panic attacks did recover; 10 of 12 depressions with anxiety attacks recovered; the depressions with puzzling recovered; the depressions with unreality feelings recovered; the depressions with agitation recovered except when cerebral arteriosclerosis was prominent, etc. The continuously alternating manic-depressive states did show a tendency not to recover; the depressions with marked hypochondriasis or invalidism showed the greatest tendency to fail to recover. This may be due in part to lack of diagnostic acumen, in the sense that except in cases under long observation it is difficult to decide how pervasive the mood is. I had the impression that continued situational difficulties might tend to prevent recovery but the facts do not seem to bear this out. Only in three cases of the non-recoveries did this seem to be true.

I studied the whole group from the point of view of mental disease background. I had to bear in mind that most of my histories were taken from the patients themselves, and that, furthermore, a positive history in this connection is more important than a negative history. Nevertheless the facts are interesting. Only a fifth of the cases had a history of attacks of mental disease in the family and this fraction was only increased to a third if one includes also unstable but non-psychotic progenitors. Two-thirds of the patients gave no history of mental disease background.

I again studied the group with reference to the number of attacks in which the patient presented himself. About one-half of the patients were in first attacks, less than one-third were in second attacks, and about one-eighth were in third attacks. These figures are not significant until one corrects statistically for (a) age grouping and the likelihood of recurrence in the one-attack group, after the seven year period studied,* (b) and the failure of some

* The average period between first and second attacks was 12 years—with a range from a few months to 29 years.

of the one-attackers to recover. Correcting for these factors, it would still appear that the chances for permanent recovery, after one attack, are at best between 30 and 50 per cent. Obviously the size of the series is too small and the period of observation too short to make statistical conclusions of this sort accurately valid.

However, in the group of over 8000 cases from the New York Hospital referred to above, the percentage ran about the same, about one-half of first attacks, one-fourth of second attacks, and one-tenth of third attacks. Unfortunately the New York series is not analyzed for age groups, is only an average period of five years, and does exclude non-recoveries from first attack.

A study of possible precipitating causes reveals the following:— 48 cases of the 144 or one-third showed no recognized precipitating factor. Business worry was assigned as cause in 29 cases; actual physical illness in 26 cases; family illness or death in 12; love involvement or overwork in 7 cases each, and scattered cases among situational disappointments, difficulty with children, childbirth, excessive responsibility, marital difficulties, etc.

Dr. Meyer has for many years stressed the importance of diurnal variation of symptoms as an important diagnostic sign in affective psychoses. Of my series 53 showed this sign; 40 of the 53 were suitable for analysis. All but 5 of these cases showed recovery. We can say that diurnal variation seems to give a slightly favorable weight to favorable prognosis. Of course the material can give no evidence as to its diagnostic significance.

In summarizing I should say from a review of 144 extramural cases of affective disorders that the Kraepelinian concept of manic-depressive insanity is valuable as indicating that the more pervasive the affect the greater the chance of spontaneous recovery, but that even predominating affectivity does not assure recovery and that admixtures of symptoms belonging to the organic, psychoneurotic or paranoid groups of reaction tend to militate against recovery but not in a definite and critical sense. The material further shows that recovery from affective illnesses may take place after much longer time than we ordinarily think. There is suggestive evidence that elation is distinctly rarer than depression and that therefore we may be including at least two different types of reaction under the one heading of manic-depressive. There is also some evidence that one attack tends to confer some "immunity" against subsequent attacks.

AGE INCIDENCE OF DEMENTIA PARALYTICA.

By MAGNUS C. PETERSEN, M. D.,
Superintendent, Willmar State Hospital, Willmar, Minn.

The age incidence of dementia paralytica among patients admitted to the St. Peter State Hospital in the four year period ending December 31, 1931 has previously been reported.[1] During the four years following, from 1932 to 1935 inclusive, there were 2271 first admissions. Both blood and spinal fluid examinations were made in all but four cases.

Clinical and serological evidence of dementia paralytica was found in 155 individuals, or 6.8 per cent. Two boys 13 and 17 years old were not included as the disease was congenital and the symptoms atypical. The Wassermann reaction of the blood was negative in 18 cases, or 11.6 per cent.

The youngest in the group was a girl aged 19. One of the men was 70 and two were 73 years old.

During the eight years covered by the two reports there were 334 patients with dementia paralytica among those admitted to the hospital the first time. Of these 246 were males and 88 females. This ratio of 2.8:1 is less than the 3.7:1 found by Wile, *et al.*[2] and the 5:1 reported by Moore and Merritt.[3]

The percentage of dementia paralytica among the first admissions decreased from 8.2 in the first four year period to 6.8 in the second. The district served by the hospital did not change nor was there any appreciable shift in the general population.

(See table on next page.)

EMOTIONAL RESPONSIVENESS IN CLINICAL INTERVIEWS.*

By JOHN C. WHITEHORN, A. B., M. D.,
McLean Hospital, Waverley, Mass.

The purpose of this communication is to report briefly some observations bearing on the emotional relationship between doctor and patient. Those who have had the time and opportunity to study closely the progress of individual patients in a mental hospital are well aware of the importance of this relationship in the care and management of the psychoses. As for the ultimate outcome, differences of opinion do exist concerning the critical importance of rapport; but within those ultimate limitations I am sure no argument is needed to persuade an experienced group of psychiatrists that a patient's emotional attitude toward his doctor makes a considerable difference in determining how good an adjustment can be made.

The much desired information about the technique for obtaining good rapport with patients remains, however, for the most part concealed behind the huge variables of personal aptitudes and unformulated experience. Even with the most earnest desire to disentangle the forces at work, for the sake of scientific understanding, the psychiatrist who is often successful in establishing good rapport has great difficulty in trying to tell the rest of us how it is done. Some of the difficulty arises, no doubt, from the fact that the development of rapport is not a separate set task but proceeds alongside of, and intimately mixed with, the other functions of the doctor-patient relationship such as the physical examination, the explanation of the hospital life, the treatment of physical ailments, the development of a daily program, the talks with relatives, etc.

One general principle can, I think, be stated with fair certainty, that the development of rapport requires an emotional reaction toward the doctor. A steady indifference blocks rapport. Any

* Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

kind of response is better than none at all. The observations which I wish to report today have a bearing on this principle. These observations do not by any means tell how rapport is developed, but they throw a certain light on the emotional responses of patients during different types of clinical interviews.

The data reported here were collected during experiments on heart rates carried on with Dr. Kaufman and Dr. Thomas.[1] I wish to acknowledge here my indebtedness to these gentlemen, and also to Dr. Helen Richter and the Mason's Committee on Research in Dementia Præcox, by whose aid the records have been analyzed. I am reporting here the observations on 12 male subjects (six schizophrenic and six depressive patients). This particular selection was made for this paper because these are the more difficult types of patient to interview. In these experiments, the patient's heart rate was continuously recorded, beat by beat, on an instrument we have called a cardiochronograph, which is electrically connected through a cable to chest electrodes. For this report, I have selected and analyzed portions of the heart record in three periods during the same session with a given patient. These sessions lasted about two hours. During one portion of this time, the patient was quietly resting alone in a room. That is called here the "rest period." It serves as a kind of "control" by which to judge the other periods.

During another period, the patient was being interviewed in the question and answer fashion, that is, a doctor quizzed the patient about his condition, his symptoms, his history, his social relationships, his sexual experiences, etc. Since the main object of these experiments at that time had been to elicit material of emotional significance, the questioning was very pointed and rather insistent. We observed a fair amount of talk and overt behavior of the kind commonly called emotional—wringing of the hands, sad expressions of the face, even a few tears, sometimes a gesture of anger, or a flushed face. The kind of interview just described is here called the "question interview."

During a third period, the patient was engaged by the doctor in casual conversation, in which the doctor participated freely, not holding himself to a questioning rôle, but making comments, listening, smiling and doing whatever seemed appropriate to keep up a free and easy conversation. The topics were quite diverse, selected

at random—political news, sports, the pictures on the walls, the pattern of the rug on the floor, the repair work being done on a neighboring building, and that old reliable topic, the weather. As you all know, it requires at times considerable ingenuity to keep up a conversation like this with the kind of patient studied. In some instances (not reported here) we had no success in this effort. These periods of informal chatting might aptly be called "talk about the weather," but they are labeled here "participation interviews."

The volume of statistical data available in the heart records in these 12 experiments is rather appalling, but I have kept the number of separate measurements down to about five thousand by selecting, by inspection, representative portions from each period for precise measurement. The characteristic of the heart record on which I shall speak here is the unsteadiness of heart rate, which is represented by a figure indicating the rate of change per beat, expressed as a percentage, that is, how much, on the average, the duration of each cardiac cycle differs from the duration of the preceding cardiac cycle.[2] For our normal controls, during interviews, this figure has a mean value of 4.4 and in rest periods 2.6.

The values of this figure, representing the unsteadiness of heart rate observed in the subjects here reported, are displayed in Table 1. Two facts are immediately seen by inspection of these

data: first, the unsteadiness of heart rate tends to increase during interviews, as compared to rest periods, although there are exceptions to this tendency; and second, the participation interview shows a greater unsteadiness of heart rate than the question interview, and this rule holds true for each subject. This difference does not mean that the participation interview produces extreme unsteadiness of heart rate, but rather that the question interview produces relatively slight unsteadiness.

Another mode of expressing these tendencies may help to fix them in mind. On the average, the unsteadiness of heart rate is 52 per cent greater in the participation type of interview than in rest periods, and this increased unsteadiness is approximately the same for both schizophrenic and depressive groups, 44 per cent for the schizophrenic and 59 per cent for the depressive. But the question type of interview raised the unsteadiness only 15 per cent above the rest period in the depressive cases. In one case, it was actually steadier during the question interview than in the rest period. Among the schizophrenics, half of them had steadier heart rates during question interviews than during rest periods, and the average increase of unsteadiness for that type of interview was only a questionable 3 per cent.

What meaning is to be attributed to these experimental findings? Our observations on normal subjects are consistent with the proposition that, for a given person, an increased unsteadiness of heart rate is an indication of acute emotional disturbance. More specific claims have been made regarding the correlation of specific emotional states with acceleration and deceleration of the heart rate (*c. g.*, Wundt and Lehmann), but these finer correlations have not been uniformly confirmed, and the statement made by Angell and Thompson [3] at the turn of the century probably represents best the bulk of the evidence. They said, "Whatever the average change of (heart) rate may be, a more uniform and, in our opinion, more significant feature is the spasmodic irregularities of the rate characteristic of curves corresponding to emotional states."

One feature of psychotic behavior makes necessary a certain discrimination in speaking of the emotional states of patients. A good many patients are found putting on a kind of theatrical show of emotion but in so unconvincing a fashion that the observer readily senses its shallowness. Some kind of a distinction needs

to be maintained therefore between the outer emotional talk and behavior and the inner emotional reaction. They are not always in agreement and not always in disagreement. The unsteadiness of the heart rate record provides an indication of the inner emotional reaction. There is no means of knowing whether it indicates the *inmost* emotional reaction, the actual feeling itself. But it gives us a tangible something to compare with the overt display. With these explanations and qualifications, increased unsteadiness of rate may be taken as an indication of inner emotional responsiveness and the experimental findings may be taken to mean, I think, that the participation type of interview elicits a more marked inner emotional response than does the question type of interview.

These experiments do not of themselves bring direct evidence bearing on the problem of rapport. They do bring evidence, however, on the relatively great importance, emotionally, of the casual participation by the doctor in the incidental interests of the patient, as contrasted with the bombardment by questions on affairs of apparently more vital importance. In this indirect way the evidence presented here tends to emphasize the relatively greater significance of the casual interchange of comments between patient and physician as important for arousing an inner emotional response and hence important in building up an emotional rapprochement between them.

SOME PSYCHIATRIC ASPECTS OF BIRTH CONTROL.*

By SARAH R. KELMAN, M. D., New York.

The question of birth control has been the storm center of church and state for many years, even today in 1937, one is somewhat timid about presenting the subject in polite society. Papers have been written and statistics compiled for and against the practice. The problem has been attacked from every angle—religious, moral, economic, social and health.

All this time the medical profession as a body was reluctant to recognize contraception as a medical problem. Every physician knows how universal is the practice of contraception, yet they failed to accept the responsibility for providing safe and efficient methods.

Strange to say, many otherwise intelligent and enlightened individuals still believe that birth control, as a social practice, began with Margaret Sanger. Few have taken the trouble to acquaint themselves with the history of contraception, although the literature on the subject is quite voluminous, some good, some indifferent. Himes [1] in his "Medical History of Contraception," published in 1936, has done a valuable piece of research. He reviewed everything that has ever been written on the subject—a most thorough, exhaustive and very revealing study. He mentions some 2000 titles of books and periodicals, and traces the practice of contraception to prehistoric man, to the primordial tribes, "of which contemporary primitive races may be said to be the social fossils." He finds the earliest written records on the subject in the Petri Papyri of Egypt, dating back to the twelfth dynasty, 1850 B. C.

Beginning with the papyrus records of more than 3700 years ago, attempts have continued, with varying success, to simplify and humanize the practice. Since the beginning of time, mankind has attempted to limit its numbers for one reason or another, first by means of charms, potions, incantations, continuing through infanticide and abortion, and various taboos on sex relations. From the

time the rôle of the male as a factor in conception was recognized, coitus interruptus played a major part.

Throughout the early Greek and Roman literature we find descriptions of various methods of contraception. During the Middle Ages, the great Islamic physicians, the Arabians, and the Persians contributed to the subject. Even the Talmud mentions embryotomy, coitus interruptus, spongy substances placed before the os, violent body movements, and potions, as methods of contraception. Curiously enough, although the early Hebrews disdained sterility, as did every primitive group, the obligation to be fruitful and multiply was not incumbent on the woman, but only on the man.

After the publication of Malthus's essay on population (1798) the medical history of contraception became intimately intertwined with the social and economic phases of that history. Thus it was in the late eighteenth and the early nineteenth century, with the sudden increased growth in population—due to industrial expansion when life was speeded up—that the birth control movement received a strong impetus.

Social agitation for birth control in modern times dates back to Francis Place and his dissemination of popular medical handbills in 1825, and to the publication of Richard Garlile's "Every Woman's Book" (1826). Place's efforts were the first organized, planned attempts in history to educate the masses in contraceptive technique.

The popularization of birth control knowledge in the United States began in 1831 with the publication of Robert Dale Owen's "Moral Physiology," And "The Fruits of Philosophy, or, The Private Companion of Young Married People," by Charles Knowlton, in 1832. Then followed a widespread circulation of birth control literature which prepared the public mind for clinics for the poor. The first such clinic in the world was opened in Holland in 1881, the second, in this country by Margaret Sanger in Brooklyn, in 1916. The storm of opposition raised by this clinic is still remembered by many. The protests from many quarters released a wave of what may be called "soap box oratory," regrettable but unavoidable. Every advance in civilization has been made over the dead bodies, if you will, of the timid, the backward, the conscientious objectors, the bigots, and the worshippers of outworn dogma.

During such struggles, brick bats are more often in evidence than silk gloves. It was no doubt during this stage of notoriety that the term "birth control" fell into disrepute, and caused conservative bodies such as the medical profession to shrink from it.

Nor is this attitude difficult to understand. We physicians are healers, not fighters. We dislike ballyhoo and notoriety. We make our scientific advances, or fights, if you please, at the bedside and in the laboratory, not by propaganda. We must, however, face the facts of history. The practice of contraception is as old as mankind itself, and is universal. It has survived through the ages in all cultures. It has survived nearly two thousand years of anathema by Christianity. Opposition is futile and foolish, no matter what our individual opinion on the subject may be. Intelligent planning of the family belongs in the framework of medicine, if not to cure disease, certainly to prevent it. In our opinion, it is preeminently a mental hygiene problem. It behooves us as physicians to face it honestly and squarely. The "lay" bodies that have done all the militant work—the spade work—are anxious and willing to turn the job over to us. Those of us who resent the intrusion of lay organizations in medical practice have only ourselves to blame. We must improve our knowledge and technique by dispassionate research and study.

It must be borne in mind that a safe and scientific contraceptive device prescribed by a physician is not a mandate not to have children—it is simply an instrument by means of which married couples may plan their families according to some rational scheme, plan in such a way that there will be no waste or drain, economically, physically or emotionally, either on the parents or on the children.

Pearl [2] in his most recent study on "Fertility and Contraception"—a study aided by grants from the Milbank Foundation—says: "Data . . . . indicate that women practicing birth control resort to criminal abortion more frequently than women who do not practice birth control." Why? The answer is obvious. A couple who decide that they will not or cannot afford any more babies will go to any length to prevent a pregnancy; when they fail with the particular contraceptive device used, they resort to abortion.

Modern psychiatry has taught us two very important lessons: first, that an adequate adjustment to life is intimately bound up

with a fair sexual adjustment; second, the concept of the total personality, the realization that human ills, be they physical, emotional or sociological, will never be adequately treated until we come to a full realization of the extent to which one influences the others. As psychiatrists, one of the most frequent and most constant symptoms we have to combat is anxiety. We are concerned with the emotional stability, not only of our patients, but of their families as well, especially the children. Individuals apparently free from intrapsychic conflict will often react neurotically to poorly discharged sexual tension; fear of pregnancy in a neurotic man or woman often plays havoc with the home and children. Furthermore, repeated failure with the contraceptive used creates a fear of pregnancy in emotionally unstable men and women, which is apt to disrupt the family.

A frigid woman will often use such a failure as an excuse to deny herself to her husband. If this proves impossible, she will seek refuge in repeated illnesses, thus driving the husband to other women or into a neurosis. A mildly neurotic man with a strong mother attachment and weak potency is often rendered completely impotent by the use of condoms or the practice of coitus interruptus, especially if an "accident" happens and conception takes place in spite of all precautions. Or, he may develop a pregnancy phobia, with everything that such a phobia may imply. Very often under such circumstances the husband is impotent to his wife, but not to other women. This leads to marital discord, and not infrequently to invalidism or divorce.

One patient who requested contraceptive advice said that she and her husband had been abstaining from marital relations for the past 10 years because they feared pregnancy and had failed with every contraceptive device they had used.

Finally, every psychiatrist knows the influence of emotional factors on the menstrual cycle. Psychotic women may develop amenorrhea lasting months or years. In the neuroses this is equally true. In the nine years we have been interested in modern contraceptive technique we have had occasion to interview hundreds of women. We found that the so-called normal woman also reacts very frequently with a delay in her menstrual period to even a mild emotional upset.

Economic expediency, physical handicaps, emotional instability, fear of pregnancy, menstrual irregularities, all seem to have a definite relation to contraception. So far, however, they have remained as isolated facts floating in the air. On the basis of our study, we are convinced that, while economic forces play a tremendous rôle, the emotional aspect of contraception is the more important.

This paper is based on a study of 400 women who sought advice on contraception at one of the birth control centers in New York.[3] These women all belong to the underprivileged group, the majority being on public relief. Yet they married, some of them as young as 15 to 17, and they all had planned babies. In fact, a large number were referred by the hospitals where their babies were born. Some were referred by various social agencies because of physical conditions which would make pregnancy a health hazard, a few were referred by mental hygiene clinics because of emotional disturbances of the patient or the husband. Some were approaching the menopause. In age, they ranged from 16 or 17 to 50. They were mostly foreign-born, or first generation American born white—Italian, Russian, Polish, Czechoslovakian, Jewish, German, and some mixed marriages. In religion, there were 253 Roman Catholics, 112 Hebrews, 30 Protestant and 5 Greek Orthodox.

This study was intensive rather than extensive in scope. Every patient was personally interviewed by the author, the contraceptive method was prescribed by her, and the patients were carefully followed for a period of from six months to three years, being reexamined at six-month intervals. Because of the psychiatric approach, we were able to elicit more information than is otherwise secured, or is necessary in such centers. The advantage of our method over the questionnaire became apparent when we attempted to evaluate and classify our data.

Certain facts came to light early in our study, notably the large percentage of frigidity, and the rôle played by anxiety in causing a delay in the menstrual period. Very often such a delay led to an abortion on a non-pregnant uterus. Today the Ascheim-Zondek test makes such guesswork unnecessary. There are still many patients, however, who have never heard of such a test, and the abortionist takes care not to inform them. One patient had 14

such abortions, which in the light of subsequent developments, proved to have been unnecessary.

On the other hand, many of our patients in their panic and ignorance are so certain that a delay means pregnancy that we have a hard time convincing them that they are wrong. The abortionist usually impresses on his patients in no uncertain terms the danger of waiting longer than 10 days. There is "danger" indeed that the patient will begin to menstruate, and the abortionist will lose his fee.

In this connection, we have had this very interesting experience on numerous occasions. A patient reports a delay in her menstrual period, and becomes panicky. Because we know her contraceptive technique to be perfect, we are able to reassure her. If she has not been using the method long, she refuses to be reassured. We then order an Ascheim-Zondek test. That night before she has had time to take her urine to the laboratory, her period is established. This has occurred over and over again in clinic as well as in private practice. Very often on the first visit patients will themselves tell us that whenever they are upset, their period is delayed. We now make it a practice to tell every patient on her first visit, "For the first few months you may lack confidence in this method or in your ability to use it correctly. That anxiety in itself may cause a delay in your period. If that happens, do not worry, but come back and talk it over with us. If you have followed directions, you need not worry."

It is pertinent to our immediate problem, namely: "frigidity and impotence in relation to contraception," to mention the various methods in vogue today:

1. Abortion is still, regrettably, too popular. We shall never know the exact number of abortions that are performed every year. According to Bromley,[4] Dr. Fred Tausig, associate professor of gynecology, Washington University, conservatively estimates the number per year in this country to be 700,000, while Rongy estimates it to be nearer 2,000,000. Our own series, although small, shows an unusually high percentage of abortions. Of the 400 patients studied, 177 had abortions; some had as many as nine. The total number of abortions was 387—178 "spontaneous" and 209 induced.

2. Coitus interruptus ranks first in importance and is perhaps the most widely used, it requires no appliances and is always available.

3. Condoms or sheaths (rubber or fish skin) are very popular. Himes [5] states that records, although not authentic, of the use of the sheath, have been found in imperial Rome. The first written mention is that in Fallopius' "De Marbo Gellico" (1564). It was first used for protection against syphilis; it then came to be used for contraceptive purposes, and by the end of the eighteenth century it was advertised publicly in England. When we realize that one million and a half sheaths are manufactured every day in this country alone, we can get a slight inkling of how widely they are used.[6]

4. Following the above three most popular methods, are a host of others much less reliable, less widely used, such as various douches, suppositories and jellies.

5. Withholding of orgasm.

6. The safe period.

7. Metal caps and pessaries.

None of these methods is very safe. Some are safer than others for some people, but there are too many sources of error, aside from objections of an emotional nature, which we shall discuss later. Of the 113 patients who practiced coitus interruptus, 61 had failed—a total of 112 failures. Of the 90 who used condoms, 32 failed 53 times. The douche was used by 23 patients, 16 failing 21 times. There then follow all kinds of combinations of the above methods plus suppositories, jellies, gold buttons, the safe period, etc.

8. Finally, the method advocated by the American Birth Control League—the occlusive diaphragm with a straight or watch spring known as the mensinga, or one with a coil spring called the ramses, and the rubber cervical cap, the most popular being the mizpah. These are used in conjunction with a contraceptive jelly which serves a triple purpose: (a) it is mildly spermicidal; (b) by its viscosity it serves to obstruct the progress of the spermatozoa; (c) it lubricates.

The rubber pessary—mensinga—was invented by a German anatomist of that name in the early nineteenth century. The inventor of the rubber cervical cap is unknown, but it appeared in England about the same time and is still widely used.

In his paper on anxiety neurosis, Freud [7] shows conclusively that the etiological factors for this clinical entity must not be sought in deep-seated intrapsychic conflict, but rather in poorly discharged sexual tension in adult men and women. Principal among the causes of such frustrations he blames certain types of contraceptives. These usually affect only one of the partners, depending on whether the wife or the husband gets satisfaction in coitus. If the wife escapes a neurosis, the husband gets it. Coitus interruptus is a well-nigh impossible method of contraception for a man who suffers from ejaculatio præcox. Even under ordinary circumstances his wife is apt to develop an anxiety neurosis; when in addition the fear that the husband will fail to withdraw in time is added to the former handicap, satisfaction for the wife is impossible. As evidenced by the impaired potency of such a man, he is suffering from a deep-seated neurosis so that the psychoneurosis of the husband, plus unsatisfactory contraceptive measures, produce an actual, or anxiety neurosis in the wife.

Condoms are not injurious to the wife if both she and her husband are equally potent. If they are not, this form of contraception is not less injurious than coitus interruptus.

Coitus interruptus is injurious to the wife if the husband pays no attention to whether she is satisfied or not. If, on the other hand, the husband is considerate and waits for his wife's satisfaction, coitus will be normal for the wife, but the husband may develop an anxiety neurosis.

Freud [8] sums up the situation in his paper on "Sexual Morality and Modern Nervousness." He states: "Thus we come closer to the question of whether sexual intercourse in legitimate marriage can offer full compensation for restraint before marriage." He concludes that it does not, "because civilized sexual morality restricts sexual intercourse even in marriage. . . . . Since all contraceptives available either impair sexual enjoyment, disturb the finer sensibilities of both partners, and even act as direct causes of illness. . . . . Under the spiritual disappointment and physical deprivation which thus becomes the fate of most marriages, both partners find themselves reduced again to their pre-conjugal condition but poorer by an illusion."

Furthermore, if, as so frequently happens, a failure results with either one or the other of these methods, the anxiety becomes so

severe as to completely incapacitate either one of the partners, or else lead to marital discord, desertion or divorce. The following case is illustrative:

About nine years ago, Mrs. G. was referred to us for advice on contraception because of a severe neurosis of the husband. The history was one frequently seen in psychiatric and psychoanalytic practice. Mr. and Mrs. G. were very much in love when they were married 10 years previously; both came from educated, cultured and moderately wealthy families. They seemed well suited and apparently destined to be very happy. Mrs. G. felt that a baby would make their lives complete, but to her surprise, her husband did not share her enthusiasm. In spite of the use of condoms, she conceived a few months after they were married, but the husband would not let her go through with it. She was too young, he said. He wanted her to have a good time before she tied herself down with babies. Very reluctantly she submitted to an abortion, but when another "accident" happened three and a half years after they were married, she refused to "do away with it." The husband stormed and raged, but it did him no good, and Tommy was born. Mrs. G. had her baby but almost lost her husband. She said, "He was passionate enough before the baby came, but I think Tommy took it all away from him." She spoke more truly than she knew. "All the time I was pregnant," she added, "he never came near me. He said he was afraid he would hurt the baby."

When relations were reestablished some time after the baby was born, coitus was reduced from three or four times a week to once a month. She said, "My husband is afraid I'll become pregnant again, and now he says he has no pleasure when using a condom. He says he enjoys coitus away from home, but not with me."

When the baby was not quite three years old, she became pregnant again, and a second abortion was performed. She was too much in love with her husband to risk his further displeasure. As it was, their life together lost much of its original bliss. Accidents continued to happen, however, and when she conceived a fourth time, another declaration of independence followed. She refused to interrupt the pregnancy.

When she came to us, Tommy was 5 years and 10 months old, and the baby, Paul, was 15 months. From the time Mrs. G. became aware of her fourth pregnancy to the time she came to us, almost two years later, her husband had not come near her. He became a changed man. Poor Mrs. G.—a normally sexed young woman of 30—was made very unhappy. To the privation caused by her husband's neglect was added bitter humiliation. She was sure her husband no longer loved her, that he must be in love with another woman. She wanted a divorce, but was too humiliated to discuss the situation with members of the family. It was the family physician who finally came to the rescue. He sensed something wrong. He pressed her for an explanation and advised a psychiatrist.

Even without a psychiatric study, it would not be difficult to reconstruct the psychopathology of Mr. G. He had a very strong attachment to his mother with unconscious incestuous wishes for her. His wife's pregnancy made her a mother—hence, "mother" whom he could not approach because of the incest taboo, and impotence was the result. Humiliation kept him from taking his wife into his confidence and made him irritable and unhappy.

Mrs. G. was fitted with a diaphragm and instructed in its use. This happened eight years ago. So far, the method prescribed has been successful—no failures reported. With the increasing security in the efficacy of the contraceptive device, Mr. G.'s interest in his wife returned, and their life together seems to be running smoothly.

It would be presumptuous to suggest that proper contraception cured Mr. G.'s neurosis, or his infantile dependence on his wife, or his jealousy of his own children. He has always been mildly neurotic but was able to function normally as long as there was no additional stress or strain. On this basis he now continues to function very well.

Huhner,[9] in discussing female frigidity, makes the statement that many men and women do not realize that a normal woman is endowed with strong sexual feeling and consequently she is given no consideration. Such women suffer in silence and never know the cause of their irritability and nervousness. Some women suffer so intensely that they often seek relief in divorce. Indeed divorce at times would prove the lesser evil. Rongy[10] claims that sexual and psychologic reactions often produce more disturbances than the derangement induced by actual pathologic changes in the genital tract. Were a psychiatrist to make this statement, it would be considered an overstatement; coming from a gynecologist, we are very ready to agree.

In their study on "Adult Sex Hygiene and Family Case Work," Lurie *et al*[11] find that instruction (in contraceptive technique) of both husband and wife helps to reduce the problems of sexual incompatibility and domestic friction by giving them a point of agreement and cooperation. The marital relation is improved also by the reduction in fear of pregnancy with its interference in the gratification of sexual relations. Any unbiased student must admit that sexual frustration, from whatever source, results in quarrels, unhappiness, infidelity, neurosis, desertion and divorce.

Admitting, then, that, as Freud says, all forms of contraception used are injurious, and that couples who for one reason or another feel that they cannot have more children, will continue to use

contraceptives in spite of their injurious effect, and admitting, furthermore, that the monogamous marriage of our present-day culture is necessary for the maintenance of our civilization, it behooves us to find a contraceptive device which will be free from the objections mentioned, a method that will, as nearly as possible, promote a normal marital relation.

In the past 17 years the American Birth Control League has been sponsoring clinics where the most recent methods of contraception are taught. We believe that that method—the use of the occlusive diaphragm or rubber cap and jelly—is the best so far discovered, and affords as nearly as anything artificial can, a normal coitus.

In our present study we have tried as painstakingly as possible to check the statement made above. We have taken, as our criterion, the frigid woman. Horney [12] in discussing psychogenic factors in functional female disorders, finds women patients who come in to be analyzed, for whatever reason, have this much in common—they all suffer from frigidity in varying degrees.

The question is, can a more superficial disturbance in sexual adjustment, such as poorly discharged sexual tension, through faulty contraception, induce frigidity? A birth control clinic should, by acting as an experimental laboratory, furnish the answer to our question.

Huhner [11] states that any condition which interferes with the full completion of the act of coitus may cause absence of orgasm and pleasure. He lists coitus interruptus and ejaculatio præcox among the causes of such absence of pleasure.

Novak [13] states that there are many women "physically and psychically normal who love their husbands devotedly and lead otherwise normal lives, and perhaps bear children, who never experience sex satisfaction."

We agree with Novak on every point except the "perhaps." There is no "perhaps" about it. Frigidity in no way impairs fertility, as is amply borne out by our present study, though many women believe that they may prevent conception by not letting themselves achieve an orgasm. Nor can frigid women be said to be psychically normal. They may not suffer from an out and out neurosis, or even complain of definite symptoms, but a trained observer will find much poorly concealed anxiety in these women.

Those of us who handle behavior problems in children have an excellent opportunity to make such observations. We can often trace the unruliness of a child to her mother's sexual frustration. Thus the child's bad behavior can, in the full sense of the word, be classed as a symptom of anxiety in the mother, even though there may be no other symptoms.

Dickinson and Beam [14] in their study found that 36 per cent of women never experienced an orgasm, 14 per cent who experienced an orgasm perhaps once in their lives, 20 per cent experienced orgasm sometimes, and only 4 per cent were said to have experienced an orgasm regularly.

Marie E. Kopp [15] in her study found that among 8544 women, 20 per cent never experienced an orgasm, 58 per cent only occasionally, and 42 per cent usually. "Occasionally" means once in a while, seldom, very occasionally, rarely, and "only a few times in my life."

It is important to note that these were apparently normal women, or at least were considered so. The information in most of the studies was obtained from either case histories or questionnaires. In our series, where the study and follow-up was conducted by the same worker, approximately the same figures were obtained, with this difference—many patients who on the first visit to the clinic said they *usually* experienced orgasm, really did not know what they were talking about. Thus after close observation over a period of a year or more, many of the patients who originally reported an orgasm usually were later transferred to the *never* column—that is, never until recently when with the security afforded by the diaphragm they experienced an orgasm for the first time. Curiously enough, many women think they are experiencing an orgasm when coitus is merely not distasteful.

Altogether 400 patients were studied. The response to the question—Do you experience an orgasm?—is shown on page 329.

On the basis of our original histories and follow-up studies we found that 80 of these 400 patients showed severe neurosis. In 34 cases the husbands were neurotic. Of the husbands reporting their reactions to the use of the diaphragm, only 10 have objected to its use. Of those patients who have been followed over a long enough period of time only 4 report a diminished orgasm as a

result of the use of the diaphragm, and 67 report the appearance of orgasm for the first time in their lives or a definite improvement in their enjoyment of coitus. In some others the observation period has been too short for the patient to feel secure enough in the use of the method to stop worrying. Of the 67 who reported an improvement in or appearance of orgasm, 21 or 28.5 per cent had never previously experienced an orgasm. Nineteen had previously reported an orgasm seldom or very rarely and 24 had previously reported an orgasm occasionally.

Of the four patients who reported a diminished orgasm as a result of the use of the pessary, one (R. La F) is definitely a mental defective. Originally she reported orgasm occasionally but said she was afraid to have an orgasm because she might get "caught," and she can never endure relations when pregnant. We had a great deal of difficulty in teaching her the method. She has been under observation for almost two and a half years, reporting at three-month intervals and during that time she reported at times an increase, at times a decrease in orgasm. She has never used the method regularly because she has a "fallen womb" and "pain." However, the husband likes the method very much, and although very kind and indulgent, is urging her to use it because he is becoming nervous as a result of using condoms and practicing coitus interruptus.

The second patient, Mrs. R. P., came for advice when her baby was three months old, her first pregnancy. Examination revealed very poor involution of the uterus. She still had a blood-stained discharge. Originally she reported that she always had an orgasm. After using the diaphragm for about eight months she reported the method satisfactory to both her and her husband, would not do without it. More recently she reports that although she likes the method, she finds that recently she has no feeling, and she is also gaining weight rapidly. She thinks this is due to the pessary. Most likely both the frigidity and gain in weight are of endocrine origin.

Mrs. M. B. came because she had two babies within one year of each other, the last one was a placenta prævia. She is very nervous and anemic, she had one period in two years, and her husband is under treatment for a luetic condition. She originally reported that she seldom had an orgasm. When she came six months after being fitted she said her husband liked the method but that she has orgasm even less frequently with the diaphragm than before; but she added, "Anyway, I am afraid to be with my husband because he has syphilis." Her syphilophobia, plus her own poor physical condition, may in large part account for her diminished orgasm.

Finally, B. J. S. is a colored girl of definitely moron intelligence. She says she usually has an orgasm but at times does not want to be bothered. She constantly complained of difficulty in using the pessary, although her technique is very good. Anyway, she had been sick, she said, and was told

she needed an operation. "Besides, he don't worry me nohow, Doctor, and I don't feel like having anything to do with my husband. If my husband never bothers me I am satisfied. But my husband likes it very much. I just has no feeling." Continued observation of this patient convinced us that she has always been frigid and when she originally said she usually had an orgasm she probably meant she had no objection to coitus, as so many women confuse absence of displeasure with pleasure.

Mrs. E. K. S. is an especially interesting case. She has been attending our clinic regularly for three years. She is said to have had a pregnancy psychosis, is extremely neurotic, and so afraid of pregnancy that she had had no coitus for six months. She had never experienced an orgasm, and did not know what it meant. This patient went through a series of episodes during which her period was delayed for two days to two weeks. Each time she returned to the clinic in a panic. "If I am pregnant, I'll kill myself," she threatened. "We are so poor and suffering so much." A series of A-Z tests, however, had reassured her and now after using the method for about three years she said, "My period is delayed but I am not worried because now I know I used it every time and I have confidence in the method." Incidentally, for a long time she used the diaphragm irregularly because she did not trust it. This is the type of patient who, if she conceives because of the irregular use of the diaphragm, will be sure to blame the method. Such a patient is usually afraid to admit her delinquency. Besides, she vainly hopes that by throwing the responsibility on the method she can induce the physician to do something. Many still believe that birth control clinics perform abortions.

Mrs. M. B. S. had many reasons to fear additional pregnancies. Her husband has a cardiac condition, and she herself has had a nervous breakdown during one of her pregnancies. At the time of coming to the clinic she complained of weakness and dizzy spells. She was sexually indifferent, although she had an occasional orgasm. Six months after the initial visit she reported that she was not using the diaphragm; said she was afraid, and would rather her husband left her alone. "I don't intend to make it too easy for him," she said. After much persuasion she promised to give it a trial. She did so, and when she made her second visit six months later, she looked like a different person. She seemed about ten years younger and much happier. At the examiner's look of pleased surprise at her appearance, she smiled and said, "You remember you told me I was nervous, I was a nervous wreck, but I am not now. I feel more secure. My husband was doing more work for a time and I could buy a few little things for myself and the children. Now he is again out of work, and the little nest-egg is diminishing, but it won't get me now. My husband won't come near me without the pessary and I *enjoy* it every time now." This patient was really a transformed individual.

Mrs. B. T. S. is another case in which both patient and husband are very nervous. She was referred to us by a mental hygiene clinic where her

husband was a patient in April, 1934. She reported "orgasm usually." It took much time and reassurance to make her use the pessary regularly. After trying to use it for about eight months she and her husband were still very nervous about the safety of the method. The husband thought he could feel the rim of the diaphragm. We kept reassuring the patient and when she came six months later, she said everything was satisfactory, "but no matter how excited I get I can't achieve an orgasm in the past two months." This patient continued to vacillate between like and dislike of the diaphragm until she had used it for a year, at which time she reported everything satisfactory. During her most recent visit to the clinic she said, "I tell you the truth. In the past year I enjoyed it better than ever before. I know when I first started using it, it took me months to get used to it. I just wanted to get through and have it over with. But now I enjoy it 80 per cent of the time, and my husband no longer comes quick."

This last patient illustrates a very important point; namely, that one has to have the psychiatric approach in order first to gain the patient's confidence, and secondly to persevere and not to be disappointed if results are not immediately obtained. It would be presumptuous to suppose that every case of frigidity or even the majority can be cured simply by proper contraceptive methods. But we must bear in mind that most of these patients are not the type that would seek psychiatric treatment. They go on being miserable and unhappy, become irritable and quarrelsome, never suspecting what ails them.

This study does teach us, however, that worry from whatever cause will induce a frigidity with neurotic symptoms belonging to the anxiety or actual neurosis variety, and that with patience and persistence the method advocated will remove this frigidity and in many cases restore a fair degree of potency in men, especially the type of man who fears pregnancy and the rivalry of his own children. The sure knowledge that he is safe from such an eventuality will remove that fear-induced inhibition, and make him function comparatively normally.

As to the safety of the method, most clinics report 90 to 93 per cent success. On first analysis, our figures seemed to correspond with the others, but on closer check up, repeated interviews after gaining the confidence of the patient, gave us further insight. In almost every case of failure the patient confessed to a slip up in the use of the method. The excuses are too numerous to mention but the excuse is always there and eventually the confession that once or twice they "took a chance." We must bear in mind that the

patients in our series are very poor, that they have very little privacy, that they are tired and harassed, and often too exhausted to bother or care, so that they take many chances. When they find themselves pregnant they are ashamed to admit their negligence.

Many cases of the so-called pregnancies were not pregnancies at all, as was often demonstrated when the patients could be induced to have an A-Z test or wait long enough for the period to be established normally. Strange as it may seem, this is not always possible. Mrs. S. H. T. offers an excellent illustration of the difficulties encountered.

She is 21 years old, married four years, came to the clinic 7-9-35, said she had had three pregnancies, two abortions of one and two weeks' gestation. (One must always take an abortion of one to two weeks' gestation with a grain of salt.) This patient did not begin to menstruate until the age of 15, the interval between periods is 30 to 54 days and the flow is very scant, lasting four days. This would suggest a mild, masked endocrine hypofunction. Furthermore, she is extremely neurotic, although she appeared sensible, jolly and contented. She said she had never had an orgasm, does not know why, loves her husband, but she guesses she would be the same with anybody. She came back six months later, very much worried because her period was a week and a half late. The period before that was 10-14-35, only the second since her baby was born. She came back 2-18-36 and said that on 12-18-35 she still had no period and went to an abortionist. She was very emotional and worried because she had had a period 1-10-36 and is now eight days over-due again. She insists she is pregnant, said she went to the same abortionist who performed the last abortion, he told her she was pregnant again. Fortunately, he refused to operate because the patient had not paid for the last abortion. She refused to have an A-Z test, insisting it was of no use. It seems to be a function of her neurosis to have abortions performed. She felt that the cost of an A-Z test would be wasted, she would rather pay the midwife. "It is the third time I am pregnant and it is all due to this method and I will not take another chance." Here she completely forgot that before she ever came to us she supposedly had two abortions. We did not hear from this patient again until 7-28-36, exactly one year from the date of her first visit. Then her sister, who is also a patient at our clinic, came in to see us. She said Mrs. T. had gone to Bellevue for a D. and C. There she was told she was not pregnant, that the trouble was due to something that was left over from childbirth. The sister said the patient would like to come back but was ashamed. 12-19-36 the patient did come back very shamefacedly. She now confesses that she had used the diaphragm only until she used up all her jelly, then her husband used a condom and this is what made her nervous and afraid she was pregnant. Nor are we at all certain that Mrs. S. H. T. will continue to cooperate.

Very deep-seated intrapsychic conflicts, not only are not resolved by the use of a contraceptive pessary, but the patients actually reject it as they reject their femininity. Such patients are devoting the greater part of their energies to escape their marital obligations. Fear of pregnancy in such women is not based on economic considerations. Rather it is a nameless fear. Such patients cannot tolerate the pessary any more than they can tolerate their husbands' attentions.

We have three patients in this series who have been using a diaphragm for from eight months to two years without telling their husbands anything about it, and the husbands are none the wiser. There is a type of man, perhaps slightly neurotic or mean, who is afraid that the use of any contraceptive will interfere with his pleasure, and he refuses to use anything himself or allow his wife to use anything. This may be so in the three cases mentioned, but their wives, being wise, are able to fool the husbands very successfully.

One husband, a very infantile, neurotic young fellow 22 years old, has given his wife much trouble. She is only 20, they have been married four years. It was a runaway marriage. They have two children, three years and fifteen months old, respectively, and are on relief. The husband refuses to use any precautions—said he did not care how many children they have; the city should take care of them. The wife threatened separation or divorce, but he only laughed at her. She finally went to court to ask for a separation, but the judge said she did not have sufficient grounds for separation. After working with this patient for about a year, we have at last succeeded in fitting her with a cervical cap which she has been using for about four months quite unknown to her husband, although he is suspicious because his wife is less nervous and fidgety during coitus.

Finally, we have had several women in our series who had a "voluntary" pregnancy. One little Italian lady decided when her sixth baby was born that her family was large enough. She was fitted with a diaphragm and used it successfully for about a year. Then the baby died. She was very much broken up about it and decided to have another baby to take its place. She gave birth to twins.

SUMMARY.

The voluntary limitation of the family is as old as the human race. The practice is universal.

It is the inalienable right of every couple to regulate the size of their family if they wish. They do it anyway.

Most contraceptives in general use are unsatisfactory, if not out-and-out unsafe, because (a) they do not always prevent a pregnancy; (b) they interfere with complete gratification and thus are apt to produce a neurosis indirectly; (c) either by inducing a delay in period due to anxiety or by an actual conception they expose the woman to the unnecessary risk and expense of an abortion. They lead to marital unhappiness, discord in the home, or even broken homes. Children in such homes have little chance to escape a neurosis.

It behooves us as physicians and psychiatrists to find an efficient, simple and unobjectionable method of contraception and make it available to our patients as a mental hygiene measure.

The rubber diaphragm, or cervical cap, as advocated by the American Birth Control League, has proved simple, efficacious and conducive to a normal sex relation; and although some claim only 93 per cent success, it has proved 100 per cent successful in this present series of cases. Any failures reported were due to lack of cooperation on the part of husband or wife, and not inherent in the method.

In 400 cases we found only 10 husbands who objected to the use of the diaphragm. From experience with patients who use it without knowledge of their husbands, we know the objection is based on an imagined interference with their pleasure, and not a real one.

Women who have always experienced an orgasm express themselves as much happier since using the diaphragm.

In our series of 400 cases, improved contraceptive methods have produced a definite return or improvement in orgasm in 28 per cent of the cases, with a consequent improvement in general health and mood, and a happier outlook on life. Even when there is no return of orgasm, the elimination of fear—the security—affords them serenity and contentment.

Many women have been saved the physical, financial and emotional strain of an unnecessary abortion.

Because it does remove unnecessary worry and relieves unnecessary tension, it makes for a more harmonious relationship between husband and wife, and a better home for the children.

It is not our intention to suggest birth control as a cure-all, but we do maintain that it is a very important adjunct to the armamentarium of every physician, especially psychiatrists, to relieve anxiety, so that the energy thus wasted may be utilized in the service of psychotherapy.

Our interest in birth control was born out of a desire to help our patients, little suspecting at first any deep psychological significance in connection with it. We had no preconceived notions either for or against its claims. Whatever of interest we found in this work was not a planned attempt at research. The facts were there all the time clamoring for expression. We are merely reporting what we saw over and over again for the past nine years.

We believe this subject merits further study and the serious interest of psychiatrists. As a mental hygiene measure, it is one of the finest and soundest investments we can make.

LUNACY AND THE MOON.

By CARL E. TRAPP, M. D., Boston, Mass.

"A lunatic, or non compos mentis, is one who hath had understanding, but by disease, grief, or other accident hath lost the use of his reason. A lunatic is indeed properly one that hath had lucid intervals; sometimes enjoying his senses and sometimes not and that frequently depending upon the changes of the moon."—Blackstone.

The concept of the influence of the moon on human welfare has its roots deep in the antiquity of our ancestral heredity. It is generally admitted that no form of idolatry is older than the worship of the moon and that lunar worship is older than solar. These old beliefs still carry much of their potency today and many are those who fear, for example, to fall asleep in the light of the moon because of possible blindness, or maintain that seed should be sown in a waxing moon and the crop harvested in a waning.

Belief in the direct influence of the moon on the human intellect and understanding forms one of the most important and interesting chapters in lunar history; it is said that the Emperor Frederick II, if he wished greater council from his wisemen, would consult them in a waning moon which, in turn, was in a human and fiery or aerial sign of the Zodiac. However, for a better understanding of this history it is best to turn to the civilizations of the past for first glimpses of the framework that was to serve as a basis for later beliefs.

The moon was the recipient of much worship for both her good and evil influence on human life. Extending as far back as the ancient mists of Egypt, Babylonia and Assyria, the moon was receiving veneration; it was held to be the sacred standard of Egyptian science and Thoth, the god of wisdom and the measurer of man's moral life, was held to be its lord. The Pyramid Texts, written during the Fifth and Sixth Dynasties, and now known to contain the earliest sacred literature of Egypt, reveal how the early Egyptian offered his prayers to Thoth, god of the moon, for greater intelligence and understanding.

Previous to the time of Hippocrates, intelligence and understanding were believed to be located in the heart—hence our expression

" to learn by heart." Therefore, one of the most frequent sacred passages to Thoth would read, " I come, I am Horus who opens thy mouth, together with Ptah who glorifies thee, together with Thoth who gives to thee thy heart (*i. e.*, understanding), that thou mayst remember what thou hadst forgotten."

In the Babylonian-Assyrian period moon worship was accorded an even higher place than solar, and again the moon was closely associated with intellect and understanding. Speaking of Sin, who was God of the Moon, Jastrow states, " The ideographs with which the name of Sin is written show him to have been regarded as the God of Wisdom; but while wisdom and light may be connected, it is Nannar's character as the ' Illuminator ' that becomes the chief epithet of the god. . . . . it is, accordingly, as the God of Light that Sin continues to be adored in the Babylonian religion; and when he is referred to, in the historic texts and hymns, this side of his nature is the one dwelt upon. Through his light the traps laid by the evils spirits, which were active at night, are revealed."

By the time of the classical era, the waxing and waning moon definitely became associated with health and disease; a decreasing moon could be used as an aid in the disappearance of disease in that it was believed that the waning moon could be obliged, by incantation, to carry disease away with it; and medicinal herbs were gathered and applied at this time. A full moon, on the other hand, was thought according to Plutarch, to be propitious to childbirth. Furthermore, Macrobius wrote that " the moon is the author and framer of mortal bodies, so much so that some things expand or shrink as it waxes or wanes."

The periodicity of epileptic attacks was soon associated with the phases of the moon and the moon was eventually held responsible in part for this disease. Aretaeus, the Cappadocian, First Century A. D., summarizes the classical viewpoints on epilepsy when he says, " But also it (epilepsy) is reckoned as a disgraceful form of disease, for it is supposed that it is an infliction on persons who have sinned against the moon, and hence some have called it the Sacred Disease and that for more reasons than one, as from the greatness of the evil; or because the cure of it is not human but divine; or from the opinion that it proceeded from the entrance of a demon into the man; from some one, or all of these causes together, it has been called Sacred."

St. Jerome was among the few who tried to stem the mystical conceptions of the influence of the moon. He stated that lunatics were not really smitten by the moon but were believed to be so, through the subtlety of the demons, who by observing the seasons of the moon sought to bring an evil report against the creature that it might redound to the blasphemy of the Creator. This apparent dissociation of the moon from madness was common at this time. In the Old Testament madness was conceived of as a phenomenon kindred to a prophetic furor; those afflicted were considered sacrosanct. However, the mad men of the New Testament were not kings but common folk and their malady is attributed, not to a spirit from God, but to inferior deities or demons, entering into them.

From the writings of Paracelsus (1493-1541), mystic, alchemist and physician, can be gleaned the great wealth of astrological and mystical beliefs of the Middle Ages. With reference to the moon Paracelsus wrote a great deal, and in his interpretations he applied both his astrological and mystical concepts. His writings demonstrate clearly the true derivation of the word *lunacy* as signifying insanity. He states, "The 'spiritus vitae cerebri' of an insane person may be attracted towards the moon in the same manner as the needle of a compass is attracted towards the pole and such a person will, therefore, especially at the time of the new moon, when the attraction is strongest, grow worse, and begin to rave; and likewise the 'spiritus sensitivus' of a man who is weak and offers no resistance may be attracted towards the moon and be poisoned by its evil influence. The moon's influence is cold; and insane people have been called 'lunatics' because they were often injuriously affected by the moon whose influence acts upon the brain and stimulates the sexual passions, and causes injurious dreams and hallucinations."

Paracelsus then gives a list of medications for the treatment of insanity, hysteria and nervous diseases. These are chiefly plants which, when collected and administered under auspicious astrological circumstances, will bring about improvement or cure. Among these plants influenced by the moon are: "Helleborus niger," "Thymus majorana," etc. He also admits with the ancients that silver is the chief metal of the moon and when used in amulets is

helpful for cure. Even today certain silver compounds have the prefix "lunar."

Throughout the intervening years the association of the moon with insanity became so deeply rooted that the word lunacy was synonymous with the word insanity. It was taken up by poets and in Othello, for example, we find:

> "The moon, coming nearer earth than is her wont, makes men mad."

Or in Hamlet the following quotation:

> "Grating so harshly all his days of quiet with turbulent and dangerous lunacy."

Physicians and philosophers admitted that the wise regulated their daily lives in accordance with the planetary aspects formed by the moon to the other planets.

Though many consider that we have now entered upon an agnostic and ultra-scientific age, the early concepts of moon influence have by no means been lost. The term "moon-mad" can be frequently seen in our daily newspapers, especially when reference is made to the activities of pyromaniacs. In a recent article Thomas P. Brophy, Head of the Bureau of Fire Investigation of New York City, admitted that, during a period of several years, more incendiary fires occurred when the moon was full than at any other time, and on bright moon-light nights he and his deputies have found it expedient to be more alert than ever.

Whatever our beliefs may be, moon lore has left its imprint on our language and not only have we our own terms such as lunacy, moonstruck, and the like, but other languages also bear the mark of moon influence. In Germany the word Mondsucht is used to signify somnambulence and, at times lunacy. The French, particularly in their Bible, frequently use the term "lunatique." However, these last vestiges of moon lore are slowly being lost to us and the term "lunacy" has been succeeded by others such as insanity, alienation, mental disease; and even our mental institutions, within the last 50 years, have changed their names from lunatic asylums to insane asylums and later to state hospitals, thereby attempting to lift a suggestive stigma from those afflicted.

NURSING EDUCATION.

By MAY KENNEDY, R. N., A. M., New York City.

The evolution of the mental hospital is most interesting history; from the dreary dungeons, the almshouses, the custodial institutions to the modern hospital where the mentally ill are receiving scientific care is a fascinating story, although at times it is heartrending. It is gratifying to those who are devoting their lives to the care of the mentally ill to see the change in attitude toward this type of illness and to know that some hospitals consider mental aspects of disease and maintain a unit for psychiatry just as they have units for medicine, surgery, pediatrics and obstetrics. In these institutions student nurses have a period of practice in this special department as a definite requirement of their course of study.

It is the purpose of this paper to discuss the care of the mentally ill as a definite responsibility of the nursing profession and to show that nursing education is incomplete unless the mental and emotional aspects of illness are given due consideration. Nurses are not adequately prepared for the practice of their profession when they are not fitted to care for all phases of illness. How often the nurse fails to recognize mental symptoms and how often she may notice the symptoms without knowing how to interpret or treat them. Many failures in nursing are usually due to ignorance in caring for the mental and emotional disturbances of our patients.

We speak of mental nursing. When is nursing "mental nursing"? It is true, there are patients who are suffering from disturbances which are pronounced deviations from normal mental well being, but even then I would like to drop the term "mental nursing" and say "nursing the patient." We do not say "physical nursing." All sick people are mentally and physically impaired and they all need the care of a nurse who understands both aspects. We who are responsible for nursing education should see that the curriculum is of such a nature that the student is prepared to nurse the whole patient, not just one aspect of the illness.

The objectives of nursing education are threefold; first, to assist students in the development of habits and attitudes of mind which

are most likely to make for adequate personal adjustment and successful living in an ever-changing environment; second, to aid students in the attainment of a knowledge of the fundamental principles and the facts upon which all good nursing is built; third, to guide students in the acquisition of nursing techniques and skills, the necessary tools of those aspiring to care for the sick.

The well-equipped nurse of today and tomorrow must have some knowledge of human nature. She must appreciate the complexity of the human organism, and realize that it is a unit composed of physical and psychological elements. The education of the nurse must be of such a character that these two aspects are given due consideration. Throughout the entire program of nursing education emphasis should be placed on studying and understanding the patient as a unit. The graduate nurse should be prepared to give attention and care to all phases of human nature. Too many nurses of today are unprepared to deal with the mental and emotional problems with which they are confronted. Nursing education has been somewhat at fault because it has emphasized the physical factors of illness with little or no regard for the mental. Schools of nursing have taught techniques for physical care and treatment and the fundamental factors underlying them; they have taught prevention of physical illness and have succeeded in producing nurses who can recognize physical impairment, interpret its significance, administer curative measures and teach physical health. The schools of the past have not given sufficient attention to the mental and emotional aspects of health and sickness, and the same is true of many of the schools of today. The new curriculum prepared by a committee of the National League of Nursing Education is emphasizing mental health and stressing the importance of including such subjects as psychology, sociology and psychiatry as required courses of the nursing school program. With nursing education thus rounded out the nurse of the future will be concerned with the patient as a whole, not just his physical well being and improvement. The integrated personality is to be studied, so that the nurse will have a better understanding of her patients and will be prepared to give them more intelligent care. A more thorough knowledge of the complicated and the intricate mechanism of human nature should aid the nurse in caring for the sick and in teaching health.

To consider the psychological factors as well as the physical in planning the curriculum of a school of nursing is to depart from the traditional and historical trend in nursing and nursing education. It will be necessary in the future for all student nurses to study mental diseases and disorders and have periods of practice in the mental hospitals, because it will be through such contacts that they will have the best opportunity of studying human nature. It is an accepted fact that studying the reactions of a mental patient is studying human behavior under a microscope.

The question that arises is what system of education will give the student the opportunity of becoming the kind of nurse who will recognize mental symptoms as well as physical, who will properly interpret and report such symptoms, who will have the ability to administer the prescribed treatment, and who can teach mental as well as physical health. At the present time there is a strong tendency in nursing education toward a combination of college and hospital resources. It is thought by many that such an arrangement will produce a nurse with a better social outlook, a better understanding of human nature and a personality greatly enriched by college experience. There is, however, and will be for many years to come, the hospital school of nursing which is owned, controlled and managed by the hospital organization. In many schools of this type the curriculum is being amplified and greatly improved by adding subject matter which will assist the student in getting a broader knowledge of people and the environment in which they live. More scientific methods of teaching have been introduced in order that learning may be facilitated.

The product of our schools must be a woman equipped to do nursing, not just physical nursing such as medical, surgical, obstetric or pediatric nursing, or just psychiatric nursing. No, it is nursing in all its aspects in which we are interested. She must understand the human organism, its growth, its relationships in a physical world, and she must know something of those factors which promote health and prevent disease. A woman who has a psychological and sociological as well as a biological background and with experience in caring for all types of human impairment will be the best prepared to meet the demands of the nursing profession. Far too long the general hospital school of nursing has emphasized physical care as the most important factor in caring for the sick,

and the psychiatric hospital has thought that psychiatric nurses could best be trained in their own institutions without any assistance from the general hospital school of nursing. It must not be forgotten that in preparing the nurse, whether in the college school of nursing or in the hospital school of nursing, the education both in content and method must be of college level. The school has a very definite responsibility both to the community and to the student who is seeking nursing education.

In order to meet State Board requirements the mental hospital school of nursing has had affiliations with the general hospital and in a relatively few instances the general hospital has had affiliations with the mental hospital. This is a beginning, but all nurses should have the soundest and broadest type of education and a thorough knowledge of human nature. The best education for all nurses is a program that will fit them for nursing the whole patient and teaching health in all its aspects. Both institutions, the general and the special, should contribute to the education of the nurse. It would seem that the ideal plan would be one where the general and special hospital cooperate with each other. The student would receive her basic education in the former and go to the latter for knowledge of and experience in caring for the acute, chronic and convalescing types of mental illness.

The mental hospital has always been jealous of its school, and rightfully so, because it has contributed greatly to the care of the patients. There is no doubt that in those hospitals where schools of nursing are conducted the nursing of the patient is of a much higher standard than in hospitals where there are no schools. A school of nursing raises the morale of the whole organization. The nursing profession, however, has always questioned the advisability of the mental hospital conducting a school of nursing, even though the affiliations were adequate so that the graduate would meet all the State Board requirements and be eligible for state registration. Some mental hospitals have advocated a course without affiliations, which leads to a diploma of "psychiatric nurse," "qualified nurse" or "certified nurse." Such a course is much inferior to the one which has affiliations and should not be encouraged. The candidates for such a course usually are young women who cannot qualify for the course leading to state registration, and who may not have the ambition to study for three years in preparation for the diploma

of graduate nurse. Either reason would indicate that the applicants were not up to the standard in intelligence and personality desired for a psychiatric nurse and would certainly not be the best type of person for the mentally ill.

In a discussion of courses in mental hospital schools of nursing without affiliations, Dr. George H. Stevenson says, " It is at direct variance with accepted standards for professional training inasmuch as specialization should follow the general training. An analogy in our profession would be the training of psychiatric physicians or tuberculosis physicians, that is, giving physicians the specialty without the general scientific background. The same principle applies in the teaching profession; the teaching specialist must first have the general training before qualifying for his specialty. It would therefore appear that the training of so called " psychiatric nurses " is pedagogically unsound, and fails to give our patients the care to which they are entitled." Every one will agree that this same reasoning may be applied to the education of the nurse.

If the mental hospital does not train the " psychiatric nurse," and if it does not have the three-year-course of nursing affiliations, what can it do to obtain qualified personnel? In no other branch of nursing is there greater need for high ideals and standards. Since a school of nursing in a mental hospital always raises the standard of care given to the patients, every effort should be made to have some educational program. The answer is a school for graduate and affiliating students. The special hospital may become the psychiatric department of the general hospital. The basic education of the nurse would be given in the general hospital and in the second and third years students would go to the mental hospital for experience in caring for patients with mental illness. The well-prepared student of the general hospital can do much in raising the standard of care given to the mental patient, and the psychiatric hospital can do equally as much in assisting the nurse in becoming better prepared for general nursing.

The mental aspect of nursing should be given attention in the very beginning of the nursing education and continue throughout the entire course of study. The curriculum should include general psychology, to be given during the first term of the freshman year if it has not been an entrance requirement. There should be short courses in study and work techniques, in personality develop-

ment and in adjustment mechanisms. Such courses will help the student in acquiring efficient habits of work and study and in building up a wholesome personality. A course in child development and in the psychology of deviate behavior will help the student to understand her patients better and prepare her to assist more intelligently in the solution of their behavior difficulties. These required courses should be correlated with practice and all case studies should include a record of the patient's mental problems and treatments, as well as a record of symptoms and treatment of the physical aspects of disease.

The time is not far distant when all members of the general hospital school faculty must be prepared to direct the students in their study of the mental aspects of illness, and teach them how to care for mental as well as physical symptoms. Nursing educators are beginning to realize that schools of nursing must consider the patient as a personality and the teaching plan must give attention to all the elements making up that personality. In addition to this broader concept of patient care, the faculty is realizing that they have a responsibility for the mental health of the student body. The personality development of the students and the solution of personality difficulties are of great concern to the teaching staff of the good school of nursing. The medical and nursing staff of the mental hospital can be of inestimable assistance to the members of the general hospital faculty in helping them become better prepared for psychiatric nursing and mental hygiene. A psychiatric consultant is always a valuable asset to any organization where groups of people are working together, and this is especially true in a school of nursing.

The first step in the organization of an education program in a mental hospital is the formation of a committee on psychiatric nursing and mental hygiene. The membership would include representatives of the general and mental hospitals, an educator, a public health nurse who knows the needs of nurses working in the homes and representatives from the boards of both institutions. The function of this committee would be to formulate policies and to promote relationships between the two organizations so that both would contribute their best towards the education of the nurse. A committee to which problems may be taken where there is opportunity for free discussion is always of mutual benefit.

The mental hospital should make a definite plan for the nursing education program. It should make an effort to have the same standards in all that pertains to the home and social life of the student as those prevailing in the general hospitals from which they receive students. The following may serve as a guide for the mental hospital faculty planning for a graduate and affiliating school:

1. An educational committee should be appointed which will make the policies governing the school. It will be concerned with the content of the whole curriculum, with the subject matter of the different courses, the methods of teaching, the selection of wards for practice, the appointment of faculty and record keeping. Every factor pertaining to the physical and mental health and personality of the student should be of interest to it.

The membership of this committee should include the superintendent of the mental hospital, the director of the nursing service, the educational director, a doctor to represent the medical staff, a nurse to represent the graduate nurse staff, the chief occupational therapist and the chief social worker.

Meetings should be held at least every third week.

2. A budget for the necessary expenses of the school should be a separate item in the general nursing budget of the hospital. The money usually given as allowance to students should be allocated to the school of nursing budget and be used for providing additional and better qualified instructors, books and teaching equipment.

3. The mental hospital should provide a faculty comparable in every way to the faculty of the general hospital school of nursing. The members of the mental hospital faculty should be given the same social and professional status as that given to the faculty in the general hospital.

4. The educational program should be planned with great care and administered according to college standards.

5. Teaching equipment should include lecture and conference rooms, laboratories with adequate equipment and material for the teaching of the various therapies used in the hospital.

6. A reference library should be provided which contains books on general medicine and nursing. Special attention should be given to books on psychology, psychiatry and allied subjects. The magazines, journals and periodicals should be general and special, professional and non-professional. The library should be part of the educational unit and a place conducive to study.

7. The clinical facilities should be organized so that the best possible practice will be available for the students.

The wards should be carefully selected so that the experience of the students will be varied and include the more important types of mental illness. They should be well equipped for good patient care and should be under the supervision of registered graduate nurses specially prepared for mental nursing and teaching.

Wards for men should be included, and under the same type of management as the wards for women. Orderlies should assist the nurses on the wards, as they do in the general hospital.

Students should have experience in all the different therapies used in the treatment of the mentally ill. They should have practice in the special departments as well as practice in the various therapies during their ward assignments.

Practice in the social service department and in the out-patient clinic should be provided.

8. The hours of class and field practice should not exceed 48 hours per week, and when students are in special departments their time on duty should be the same as that of the personnel of that service. A whole day off duty each week should be given to the students when on ward duty.

9. A physician of the mental hospital should be in charge of the health of the students. Emphasis should be placed on personal mental hygiene and every opportunity taken to teach mental health.

10. The mental hospital should provide adequate living quarters for the faculty and students of the school. If it is not possible to have a separate building, then one wing or a section of the nurses home should be set aside for their exclusive use.

The residence should be in charge of a capable and experienced director who has an understanding of young people and is interested in making their home life wholesome and congenial.

A program for recreation and social activities should be provided.

11. The school should have a record system of student attainment, efficiency and personality, which is comparable to the record system used in the general hospital school of nursing.

The care of the mentally ill and the prevention of mental illness are two important problems confronting society at the present time. A satisfactory solution involves hospitals, doctors, nurses, therapists of various types, social workers and other personnel. The nurse occupies a most strategic position for she is with the patient the full twenty-four hours and works in the hospital and in the community. She not only assists in the treatment of the mentally ill, but aids in the promotion of mental health and in the prevention of mental illness. Every effort should be made by both general and mental hospitals to cooperate in organizing a system of education which will offer the best kind of preparation for nursing in all its varied aspects. Each institution should contribute that for which it is best fitted. The general hospital should teach fundamental principles and provide practice in general nursing, while the mental hospital should teach psychiatry and allied subjects and provide practice in the care of the mentally ill.

I am confident that if all general and mental hospitals in a state would coordinate their resources the future nurse would be more adequately prepared to serve the public. The nursing care in both the general and mental hospital would be of a higher standard and the public health nurse would be better equipped for nursing and promoting mental health in the community.

DISCUSSION.

DR. GEORGE H. STEVENSON (London, Ont., Canada).—The Association and the Committee on Psychiatric Nursing is very much indebted to Miss Kennedy for coming today to present this interesting and very challenging paper. Her prominent place in the nursing world as Chairman of the National League of Nursing Education's Committee on Psychiatric Nursing and Mental Hygiene is some indication of the attitude taken by the official nursing organizations. She presents to us the thesis that there is no natural division of physical and psychiatric nursing. At first glance, this appears a revolutionary statement, interested as we are in our attempts to see that mental patients are properly nursed, and interested as we are in trying to persuade nurses generally that those under our care are actually sick and require nursing.

We have come a long way in recent years in both of these developments. As psychiatrists we no longer differentiate physical and mental, but are interested in the individual as a whole, the sick person. We can, therefore, commend strongly Miss Kennedy's attitude and the recognition of the nursing profession generally that the mentally ill are ill, acutely ill, even deliriously ill, and are entitled to the best nursing care.

The extent of this recognition may be indicated by the results of a survey conducted by our Committee on Psychiatric Nursing during the past few months, revealing that 288 general hospital training schools in the United States and Canada give actual experience in this field, either by affiliation with a mental hospital, or by a psychiatric ward or division in the home school. Compare these figures with the very few schools that gave such training even five years ago.

If we accept this general thesis, the practical means by which nursing education is to be developed must receive hard thinking. Undergraduate schools in mental hospitals sprang up for the same reasons as in general hospitals, although somewhat later. Those of us who have seen the development of such schools well appreciate the great value they have been and the better care our patients have received as a result, especially our women patients, because curiously enough some of us did not realize that sick men required just as good care.

Neglected as we were by nurses trained in general hospital schools, our own training schools had every justification. Miss Kennedy suggests that such schools be now discontinued. This makes a very distinct problem for

us, because of our dual responsibility as hospital administrators on the one hand, and on the other, nominally at least as heads of our schools of nursing.

It certainly is our duty to see that our patients are well nursed, but it is equally our duty to see that our schools of nursing, if continued, are adequate. We have no right to operate such schools if they are not giving adequate education to the nurse, or if they are exploiting the nurse, or serving as a means of getting cheap labor. If the apprenticeship system is to continue for a time, at least, we expect service from our nurses. Such service should be incidental to the business of training her to give adequate service after graduation.

Many mental hospitals are discontinuing undergraduate schools. The reasons for such actions vary. If a hospital cannot give adequate training even with a general hospital affiliation, it has no right to continue; however, most of the schools which have discontinued have done so in favor of affiliate and postgraduate training, because of the belief of those in charge of them that the time has come for adoption of the views expressed by Miss Kennedy in her paper.

The Committee on Psychiatric Nursing has also ascertained during the last year that there are 60 affiliate courses, and 33 postgraduate courses of psychiatric nursing offered in the United States and Canada. Only 46 undergraduate schools accredited by this Association are still operating, compared with over 60 as recently as two years ago.

We are witnessing a very new and definite trend in nursing education in mental hospital schools of nursing. If we are to discontinue our under graduate schools, there are certain questions that we will want to ask Miss Kennedy and ask ourselves. What assurance have we that an adequate supply of nurses will be available for our ward needs? What salaries are to be paid, having in mind that most of our hospitals are operated by governmental agencies? How far will general hospitals go in insisting that their nurses receive psychiatric training? As I mentioned, 288 schools and general hospitals are now offering that training, but that is a very small fraction of all the general hospital schools operating in these countries.

Obviously, this change cannot be made suddenly. It does appear to be in progress, however, judging from the figures quoted. We shall probably need to have schools in some psychiatric hospitals for some time yet to supply our needs, at least until all nurses are definitely trained and psychiatric nurses are available and willing to enter the service of the mental hospitals.

The Committee on Psychiatric Nursing does not advise or recommend the discontinuance of training schools in mental hospitals until such time as each hospital can be assured of satisfactory answers to the foregoing questions.

As a result of the survey of certain schools of nursing, accredited by the Association made by Miss Harriet Bailey, and reported in the *American Journal of Nursing* and in THE AMERICAN JOURNAL OF PSYCHIATRY in January of this year, the need of looking to our standards has been forcibly brought home to us, although Miss Bailey did not go quite so far in her recommendations as Miss Kennedy has suggested in her paper, but the problem is there and it cannot be ignored.

THE IRRITATIVE TREATMENT OF SCHIZOPHRENIA.

Review of 20 Cases.

By EMERICK FRIEDMAN, M. D.,
Stony-Lodge, Ossining-on-Hudson, N. Y.

Introduction.

The treatments devised in the past for schizophrenia are as numerous as the concepts of its etiology and both are constantly changing with the times. It is the purpose of this paper to present for consideration a recent trend in its treatment, approaching the problem from the organic or physiologic aspects. It is well at this point to state summarily that many workers [1] have determined that there are changes in the metabolic and chemical processes in schizophrenia. These changes, although minimal, do indicate that there exists a type of sluggishness, as it were, in the bodily economy of schizophrenic patients. This sluggishness may be translated theoretically in terms of lowered metabolic activity of the brain. It is possible to theorize further and state that there may be a functional barrier to facile absorption or assimilation of nutritive elements set up in the brain of such a patient. The mental changes resulting from this barrier would become proportionately irreversible as the disease progresses. A therapeutic routine directed against this functional barrier before actual irreversible changes have occurred may reinstate the normal nutritive mechanisms thus providing an unblocked pathway for normal mental functions.

Theoretically then, we may state that the following therapy is in the nature of an irritative or stimulative means to combat this blocking. According to v. Meduna [2] the irritative therapy of schizophrenia involves the setting up of a temporary epileptic state by the use of convulsive drugs. This is based upon the study of a large number of schizophrenic and epileptic patients, and the noteworthy finding of a very infrequent concurrence of the two conditions; in other words, a type of biologic antagonism similar to the

one noted between febrile conditions and general paresis. Whether or not the actual motor reactions occurring with the therapy are necessary for improvement or remission cannot as yet be stated. Among the 110 patients treated by v. Meduna those who reacted readily with convulsions showed the most favorable and the earliest remissive changes.

The procedure described by v. Meduna was modified to some extent and carried out in twenty cases admitted to the psychiatric service of the Buffalo City Hospital, during the routine 30-day observation period.

Method and Rationale.

Part A.—The diagnosis is established as soon as possible and the patient's family contacted to explain and receive consent for the therapy. Complete laboratory work is done, with the blood chemistry values and complete urine determinations once weekly. The patient is placed on standard alkaline diet arranged by the dietitian. The diet must include adequate vitamins, calories and bulk. He is given 1.30 gm. sodium bicarbonate three times a day. The urine is tested daily for alkalinity to litmus during the first five days; thereafter twice weekly for the extent of the treatment. Fluid intake is set at a minimum of 2 liters per day. No sedatives of any type are given during the period of treatment.

Part B.—The two convulsant drugs employed are camphor in the 25 per cent oily solution given intramuscularly, and metrazol * given in 10 per cent aqueous solution intravenously. A freshly prepared sterile solution of camphor is injected twice daily only after the urines have been alkaline for two days. The initial dose is 16.0 cc. (4.0 gm.) and the subsequent doses are increased at the rate of 4.0 cc. (1.0 gm.) per day. When metrazol is used the injections are given once every other day starting at 5.0 cc. (0.5 gm.) and subsequent doses are increased at the rate of 1.0 cc. (0.1 gm.) each injection. When camphor is employed and convulsions occur at any given dose the injection is omitted the following day, and the next dose is the same as the convulsing dose. If convulsions do not occur after four injections, three or four days are allowed

* Pentamethylenetetrazol.

to elapse before the injections are resumed, and then at an increase of 4.0 to 6.0 cc. The maximum dose of camphor is set at 56.0 cc. (14.0 gm.). In the case of metrazol the doses are increased as stated whether or not convulsions occur. The maximum dose is set at 16.0 cc. (1.6 gm.).

When convulsions occur, the patient receives the routine (immediate) care usually given epileptic patients excluding the use of sedatives. In the case of camphor, convulsions were found to occur from 15 minutes to 3 hours after the injection, and as high as 6 individual convulsions were noted. When metrazol is used, only a single convulsion immediately ensues and prompt attention must be given. The dosages suggested above are flexible. When convulsions resulting from any given dose are unusually severe or prolonged, the subsequent doses must not be increased as rapidly as stated. The individual reaction to a given dose is the sole determinant of subsequent doses.

The following observations are charted: (a) Occurrence and description of convulsions as to number, severity and whether they are partial or general. The phases are noted as well as the nature of the post-convulsive state. (b) Occurrence of irritability when annoyed or bothered by others, as well as coöperative attitude. (c) State of activity: whether or not accessory phenomena are intensified and muscular and impulsive activity are increased. The patient is frequently interviewed and any mental changes noted.

Due to the short time during which the patient is available for study, adequate opportunity is not given for a long and minutely detailed study and almost a dramatic result is necessary to demonstrate the efficacy of the treatment. It is seen, therefore, that a rapid establishment on an irritative threshold, and one without danger to the patient is of ultimate importance. This threshold may logically be reached by the administration of alkali to reach as thorough a degree of alkalinization as possible. It is known that alkalinization is tetanic or convulsive in itself.[3] Likewise the administration of an adequate amount of fluid assists in the maintenance of an irritative background in the central nervous system. These principles are well known in their converse relations in the more or less routine treatment of epilepsy, *i. e.*, ketogenic diets and dehydration.

As to the dosage of camphor and its tolerance-variations, it was determined by v. Meduna that convulsive doses vary not only in different patients but also in the same patient at different times. It was observed in this study that camphor does not always produce convulsions but its therapeutic value is still present as will be shown later.

Without going into great detail regarding the actions of the drugs employed, the following clinical observations have been noted in this work. With metrazol, an immediate, typical epileptiform manifestation appeared, simulating true epilepsy in all its well-known phases, including vivid auræ and automatisms. At the initial stage of the convulsion there was always a tonic yawning movement which was utilized to insert a thick gauze pad to prevent tongue-biting. When camphor was employed, the reactions were manifested over a longer period of time. Single or multiple convulsions occurred after a much longer interval and usually without warning. Whether or not convulsions occurred, there was noted what may be called a deliriform or twilight state somewhat similar to that of an individual mildly under the influence of alcohol or cannabis. The patient would walk about as though dazed; reactivity to vivid and painful hallucinations chiefly of the somatic type was frequently noted—different in many ways from the reactivity and the content of the hallucinations noted before treatment was started. This difference was noticeably significant in that the patients registered concern and anxiety about the hallucinations. It was not infrequently observed that impulsive activities were increased, and the patient would become destructive and aggressive. In many instances, the only descriptive term possible was that the patient was "different." These reactions to camphor and somewhat less to metrazol remained for as long as ten days after the last injection. The patients would state, when they returned a month or more after release, that they recalled only fragments of what went on while they were under treatment. They would recall the intense auræ and how terrified they felt "just before going to sleep" (onset of the tonic phase of the seizure). Petit mal types of seizures were frequently observed with metrazol and similarly, but with much less frequency, with camphor. In these cases the patient underwent a restless type of gross twitching for one or two seconds and this

was immediately followed by a period of intensely vivid hallucinatory reactions, lasting for as long as two hours. It was often extremely difficult to persuade the patient to verbalize these reactions, but the staring, fixed expressions of terror or pleasure left no doubt as to what was occurring.

The immediate obnoxious effects of camphor, and to a much lesser extent with metrazol, were nausea, emesis, a mild form of ataxia and infrequent complaints of malaise and paresthesia-like pains in the extremities. The only complications noted in this series were two cases of bilateral subcutaneous abscesses in the gluteal region, resulting from the camphor injections, two cases of moderately severe tongue lacerations, and one case of a dislocated mandible due to the tonic yawn with a metrazol convulsion. v. Meduna reported, in addition to these, only one case of a dislocated shoulder due to a severe convulsive reaction.

The contraindications, as listed by v. Meduna, are: (a) failing or decompensating cardiovascular system, (b) any acute febrile condition, (c) menstruation. To these we added: (d) severe anemia or cachexia, (e) any abnormality of the blood or urinary constituents, and (f) previous history of severe cranial injury with subsequent unconsciousness.

Typical Case Reports.

17. I. F. Slavonic female. In the six years before the present admission, this patient has had untoward, purposeless, impulsive reactivity to more or less well-defined erotic delusions. She has had three previous admissions to the psychiatric service followed by two admissions to the state hospital with paroles and discharges each time. The last discharge from the state hospital was about six months before her present admission to Buffalo City Hospital. During this interval, the patient gradually reverted to the same behavior as described above. She became less and less efficient in her home until she was a hindrance to ordinary domestic routine. On her present or fourth admission, she was brought in by the police who found her in a grocery store, where she had been sitting for several hours, grinning foolishly and giving no answers to questions. In the hospital a considerable amount of emotional deterioration was noted together with the other signs previously mentioned.

Camphor was administered from the fifth day after admission, and there resulted a continuous, confused, deliriform state punctuated by rather severe convulsions. On examination at the end of her term, she was quiet, pleasant and well-behaved. There were no delusional manifestations and she was rather cooperative and helpful. The patient was regarded as much improved

TABLE III.

RESULTS.

Case: Name and No.	Immediate results.	Results after two or three months.
J. S. 8	Somewhat improved, much more cooperative, not impulsive, defective judgment.	State hospital—developed true catatonic state.
F. M. 9	Unimproved—unchanged.	State hospital, much more cooperative and helpful. Occasional outbursts.
A. O'B. 10	Cooperative, quiet, no hallucinatory trends. Much improved and released.	Good social adjustment. Employed.
N. W. 11	Speech retardation and confusion. Cooperative and helpful. Good planning ability. Much improved. Released.	Retardation of speech. Still cooperative.
L. M. 13	Quiet, cooperative, no delusional trends, no planning ability, somewhat improved. Released.	First month worked, was sociable and helpful, then again argumentative and irritable. Recommitted.
P. W. 14	Confused, deliriform reaction on release.	Very well adjusted socially, behavior extravert employed. Much improved.
C. S. 15	Alert, cooperative, no accessory symptoms. Much improved. Released.	Employed. Well adjusted at home.
G. K. 16	Cooperative, interested in family, no hallucinatory or delusional trends. Much improved. Released.	Has not been heard from.
I. F. 17	Quiet, pleasant, well-behaved, no accessory symptoms. Much improved. Released.	Well adjusted socially. Employed.
A. S. 19	Normal concern over domestic affairs. No delusional trends, cooperative, friendly. Much improved. Released.	Rapid relapse to original condition. Committed to state hospital.
G. S. 20	Relevant and coherent speech, fair planning ability, immature emotional attachments. Much improved, released. No accessory symptoms.	Sudden relapse to original disturbed state.
C. W. 21	Quiet and cooperative, no accessory symptoms. No insight nor plans. Much improved. Released.	Alert, stable, considerable insight, well-adjusted socially. Ready to work.
E. Z. 22	Apathetic, confused, released under camphor.	Alert and spontaneous. Eager to work. Well adjusted at home. Much improved.
W. M. 23	Retarded speech, cooperative, helpful, much improved.	Well-adjusted socially, friendly, had conclusive plans regarding going to work.
E. S. 24	Condition unchanged. Unimproved.	Not contacted as yet.
F. W. 25	No accessory symptoms, confused, cooperative and helpful. Much improved. Released.	Friendly, well-adjusted, considerable insight. Planning to carry on studies.
G. H. 26	Confused, no accessory symptoms, cooperative and helpful. Much improved.	Alert, spontaneous and rational. Some insight, well-adjusted socially. Eager to work.
I. C. 27	No accessory symptoms, speech rational. Superficial and evasive. Much improved and released.	Well adjusted socially, considerable insight, resumed active work.
F. D. 28	No accessory symptoms, speech coherent, emotionally unstable and deficient judgment. Unimproved but released.	Rapid relapse, is being treated again.
W. G. 29	Some retardation of speech, quiet and cooperative. No accessory symptoms. Much improved. Released.	Well-adjusted socially. Alert and spontaneous. Eager to resume work.

and was released. After conversing with her, her people were only too glad to take the patient home, whereas previously, they had insisted on prompt hospitalization.

She was seen one, and two months after release. She was dressed well; her appearance was improved by the addition of partial dentures, and she talked eagerly and in a straight-forward manner. There were no accessory symptoms and she had been usefully occupied at home and in the family's store. Three months after release the patient telephoned and stated that she was feeling so well, that she felt it unnecessary to fill her appointment. Besides, due to her work, she did not have time for it.

27. I. C. American male. This patient had a residual atrophy of the right leg and left thumb since an attack of poliomyelitis in childhood. He had been a high school instructor in mathematics for several years before admission. For two months before admission he had been working very strenuously, organizing a teachers' union, lecturing and diligently working for a Ph. D. He began to complain of fatigue about two weeks before admission, at which time he remarked that he had done an injustice to his students. Instead of helping them just before mid-year examinations, he stayed at home to rest. He was at home for about a week and then returned to work. Three days before admission he fainted while teaching, and was brought home from school. On the following day he acted very queerly toward his family, expressing ideas of suicide, and he appeared very agitated. Early in the morning of the day of admission he awoke and quoted passages from the Scriptures mingled with nursery rhymes. He also suffered from persecutory hallucinations and held arguments with his imaginary tormentors, later becoming threatening and aggressive. He executed various purposeless and protective manœuvers. After admission, these actions continued. He attempted frequently to void in the corners of his room. The hallucinatory manifestations continued.

He was placed on metrazol therapy on the third day and responded with violent convulsions with each injection. After the second injection he displayed no further hallucinatory reactions and was well-behaved. He walked about the ward with a dazed expression; he tried to read the newspapers but it was apparent that he had difficulty in comprehension. Examination at the end of his term brought out no accessory symptoms, and his speech was, for the most part rational in all fields. He was, however, superficial and evasive regarding his hallucinatory and disturbed period. He was amenable to suggestions as to his future. He was regarded as much improved and was released.

It was learned from the patient's family physician that he had not only adjusted well at home, but that he had returned to active work in school. He did not return to the out-patient department because he felt ashamed of being regarded as a "former mental patient."

Two interesting points may be mentioned about this patient: his willingness to verbalize his sensations while receiving the injections and his interest in his condition after release. Regarding the first point, he would give the following description: at first, he would have a penetrating sensation of an

odor similar to ether, which seemed to pervade his entire body; then he would experience a buzzing in his ears, and he felt as though he swam in the air; this was followed by a feeling of being violently tossed about, in the midst of which the tonic phase of the convulsion ensued. This sequence was repeated with each injection. As to the second point, the patient secured a copy of his discharge record from the hospital, and went to the library to look up for himself what the term "schizophrenia" meant. When he found out, he went to his family physician and argued with the latter so logically about this question that the physician stated in an informal conference, that it was hard for him to believe the patient was ever afflicted with a mental illness.

29. W. G. Teutonic male. The patient was a civil engineer who had worked hard, supporting himself through his school years and had readily obtained employment after graduation. About two months before admission, he obtained an advanced and responsible position which necessitated temporary separation from his family. The history of the onset of his condition was unclear. All that his family could find out was that the patient had insisted on going to church in his pajamas and that when placed in a nearby hospital he became so unmanageable that his employers had to bring him back to Buffalo. He spent about one week in a private sanatorium in Buffalo, and after several escapes through the window in response to "voices of his school-mates," he was admitted to the Buffalo City Hospital. On the ward he was aggressive, striking at nurses and attendants. He frequently stood by the window, staring at the sky for long intervals, a worshipful expression on his face. Upon questioning, he would give long, irrelevant philosophical and religious monologues.

He was placed on metrazol therapy, and responded with severe convulsions. With the first convulsion, he suffered a dislocated mandible. On subsequent injections this was prevented by inserting the tongue-pad before administration and holding his jaw firmly closed during the tonic phase. After the second injection he became more cooperative. With subsequent injections he ceased to stare out of the window and was somewhat helpful about the ward. Gradually his conversation became more relevant, although he could not understand why he was given the injections and why he had to be in the hospital. Examination at the end of his term revealed no delusional trends; he had only fragmentary recollection of his conduct on the ward. His responses, although relevant, were slow and lacked spontaneity. He displayed a meaningless, superficial smile and his comprehension appeared slow. He stated that just before he came to the hospital, he had felt that his mind was clear and that he felt like "acting as though he were a child." He could not elucidate this point. He was regarded as much improved and was released.

He was seen in the out-patient department three weeks after release. He was well-dressed, carefully groomed and greeted the writer in a very friendly fashion. He spoke alertly, spontaneously and in a straight-forward manner. Although he could recall but very few incidents of his hospital period, he had been informed of his actions by his wife, and he was very grateful. He gave a concise story of his life, and how hard he had had to work on his job. He

said that he had had to work all day and study until late at night on the engineering theories involved in his project. He had had no vacation for ten years preceding this illness. He stated that, looking back, he could feel this illness "coming on" for six months preceding admission. He felt himself getting increasingly restless and afraid he would lose his position; he would find himself suspecting his subordinates of trying to make the work difficult for him—all of which he evaluated properly as imaginatory phenomena. He eagerly discussed plans for the future with especial reference to vocational and recreational activities. Two weeks later, he wrote a friendly, coherent letter, stating that he felt very well and had obtained his former position. He asked that we advise him more specifically as to hours of rest and recreation.

19. A. S. Teutonic female. For seven years before admission, the patient had been undergoing personality changes. She became quarrelsome, domineering and irritable. She flew into a rage if her husband so much as drank a single glass of beer. (He was not an alcoholic.) She had threatened to leave him several times for no apparent reason. She became involved in many religious cults, studying one after another. She memorized and quoted lengthy passages from the Bible to friends, neighbors and family. She continually harped on the subject of "saving" everybody. Her answer to all financial and domestic emergencies was that the Lord would help her get along. She incurred many purposeless debts and became angered if called to task for them. During several days before admission the patient became hopelessly unmanageable. She went to church and loudly berated the minister in front of the congregation, and then went home and threatened the children, whence she was brought to the hospital. On the ward she displayed an angry, lordly air and denounced everyone connected with her commitment. A religious, delusional trend was apparent and an uncooperative, noisy attitude characterized her behavior.

Camphor therapy was begun on the eleventh day after admission; she was given large doses without any convulsive response. However, a confused, deliriform state ensued in which the patient complained of many somatic hallucinations. The domineering character changed to one of silly emotional actions at times mingled with destructive or combative tendencies. Near the end of her term, the therapy was stopped because of the development of bilateral subcutaneous abscesses in the gluteal region. With proper surgical procedure, these subsided. Meanwhile, the patient became much clearer mentally; she began to display a normal emotional concern over domestic affairs. She made many good-natured and friendly remarks about the ward routine. On examination she neither admitted nor recalled any delusional trends. She remembered none of the incidents immediately leading to her hospitalization. Both she and her family were advised regarding further therapy, but this was refused. The patient was regarded as much improved and was released.

One week later, she was visiting relatives and in the course of an argument, she suddenly became over-active and aggressive; she was then committed directly to the state hospital.

11. N. W. Teutonic male. For four months before admission he had been getting increasingly inert and seclusive. One week before admission, after a severe scolding by his father, he suddenly became mute and bed-ridden. He refused nourishment and was frequently incontinent during this time. He remained in this state after admission. Due to the difficulty in contacting the patient's family (they lived some distance out of town), the diagnosis and treatment were deferred for several weeks. In the hospital he assumed typical catatonic attitudes on several days, and on a few occasions he had outbursts of aggressive behavior. He had to be fed by the attendants.

Several weeks after admission he was started on camphor therapy, and responded with violent convulsions. After the first seizure the patient wept for a few minutes. After the third seizure he began to talk, got out of bed, and ate without assistance. With subsequent treatment he took more interest in his surroundings, tried to be helpful about the ward, and kept himself neat in appearance. Examination at the end of his term revealed a certain amount of retardation in his speech as well as a considerable amount of confusion as to what went on during his disturbed episode. He stated that he was "very sick" and "must have been delirious" during that time. He planned to go to work on a farm until he got stronger and then he wanted to go to work in a factory and attend night school. He was regarded as much improved and release was recommended. At this time, the patient contracted scarlet fever and was transferred to the communicable service for five weeks. He was seen at the end of that period. The retardation of speech had disappeared and his behavior had continued to be satisfactory. He still intended to carry out his plans as mentioned above. He was released when his infection had subsided. He has not kept his appointments to the out-patient department.

24. E. S. Slavonic male. According to his parents, the patient had a sudden onset of talkativeness, restlessness and insomnia three days before admission. He talked for hours at a time about his superiority to everyone else and declared that he felt everyone was an enemy. There soon followed delusions and hallucinations (from the description given by the relatives) of the erotic and religious type. On the day of admission he put his hands into the oven and proclaimed that due to his "power" they would not burn. In the hospital he continued to have erotic and religious delusional trends. He was talkative and restless. He had to be watched constantly because he would either take off his clothes or else would void openly and indiscriminately.

He was placed upon metrazol therapy on the fourth day after admission and responded with only a meager number of severe convulsions. His behavior and speech showed no improvement; he was committed to the state hospital. An interesting feature in this case was that in all his grand mal type of convulsions, he displayed no automatic phase; after the clonic phase he would have a brief period of somnolence. With every petit mal reaction, he assumed characteristic praying attitudes and when questioned, stated that he saw naked women on the walls.

22. E. Z. Teutonic male. For over a year before admission, the patient had been getting increasingly seclusive and preoccupied. Several months before

admission, he stopped working because of vague complaints about his teeth. He did not consult a dentist, however, but just stayed at home sitting in his room. He would go for days without talking and frequently would walk to the window and would look out as though in expectation. On other days he would pace the floor rapidly, lie down for a moment only to jump up again. He frequently went to the sink and drank water day and night. On admission, he gave a long, evasive account of how his system was poisoned by his teeth, and that was the reason for his quitting his job. He was also evasive about his actions at home. No definite hallucinatory or delusional trends could be elicited.

Camphor therapy was started on the fifth day after admission and he responded with confused, apathetic state that occasionally changed to an excited and destructive reaction. He had no convulsive response until the last day of therapy, when he had four successive seizures. The patient was committed to the custody of his mother at her insistence and he was released while still under the influence of camphor.

He was seen one month after release. The confused state due to the camphor had entirely disappeared. The patient was alert and spontaneous. His speech was straight-forward. He could not recall any of the details of his hospitalization except that he felt "awful sick to his stomach" and vomited frequently (true). He showed evidences of being irritated by his mother's constant attentions to him, and he begged to be allowed to work again. He willingly entered a discussion about recreational activities and cultivating friendship. He was sincere in his promises to follow suggestions.

Discussion of Results.

Twenty cases of schizophrenia of the types listed were treated by the irritative therapy as described. In eleven cases the convulsant drug employed was camphor, in seven, metrazol and in two, both were employed. The selection of drugs was arbitrary. The small number of cases precludes the establishment of percentage values or averages. Of these cases there were fifteen who improved sufficiently to be allowed to go home; two cases were improved to a lesser extent and state hospitalization was still necessary; three cases were unimproved. In the first group, two cases who were rapidly recommitted after release, ought to have had more therapy. In most cases the drugs employed are not entirely eliminated from the body for at least ten days after the last injection,[2] and any improvement while still under the intoxicating influence of the convulsant drugs ought to be tested, as it were, by allowing the patient to eliminate the drugs in order to obtain a more correct, "non-irritated," mental status. In the present hospital set-up, this

is rendered very difficult because of the time limitation. In two cases (16 and 25) whose periods of treatment were far in excess of 30 days, it was made possible by transfer of the patient to the neurological service and conducting the therapy and observation there. In the other cases the period of treatment closely approximated the 30-day period. It is interesting to note that in this series, improvement occurred in four cases whose illness had been present over two years, and one case whose illness had been progressing for at least six years. The importance of the combined effect of the deliriform state and convulsive responses is illustrated in cases 19 and 22. The former developed only a deliriform response and improvement was temporary. In the latter case the deliriform response alone was noted up to the last day of his term, when he had four successive convulsions; his improvement has persisted. The complications have been mentioned before. Although we mentioned the laboratory and physical findings only in the sense that we were attempting to exclude contraindicatory factors, these findings were repeatedly checked; but to conserve space we may only mention that not even suspiciously pathologic changes could be detected in the course of the therapy. This is in accordance with the more extensive investigations of v. Meduna.

Comment.

Although the therapy may appear radical in the sense that an induced deliriform and convulsive state is viewed with alarm by the laity and general practitioners, yet the same phenomena are thought of in a rather complacement light if they occur with spontaneous regularity as is the case in true epilepsy. The variability of convulsive doses of camphor (tolerance) is of practical importance and patients who may have had several convulsive responses to lesser doses, *e. g.*, 5.0 to 6.0 gm., may not have any convulsions with such large doses as 10.0 to 12.0 gm. The convulsive level with metrazol, when once established, was easily maintained. The question arises as to whether or not the actual motor responses are necessary for the production of improvement. This cannot be answered by this work. However, with rapid establishment of convulsions, improvement was proportionately rapid. It is felt that the profound psychic upheavals occurring with the

petit mal type of reactions are of importance as well as the deliriform states that were noted especially with camphor. The psychomotor upheaval as a result of a grand mal type response was only too apparent: whereas little or no emotional response could be elicited before a seizure, a rather tearful or frightened reaction often followed it. While it is, as yet, difficult to evaluate the individual importance of motor or psychic upheaval we must consider that both elements are necessary.

As to the number of convulsions necessary for improvement, the following rule was adopted by v. Meduna: the therapy should not be interrupted until 15 to 20 convulsions have been obtained regardless of the clinical state of the patient during the course of the therapy. Or else, *at least* three additional convulsions should be obtained after improvement is apparent. In this work we have had to condense our treatment to conform with the time limitations. Whereas v. Meduna administered the drugs to obtain convulsions twice weekly, we conducted the routine so as to obtain seizures, as near as possible, every other day, and to produce a continuous deliriform state between seizures.

The duration of the illness before treatment is important. As is well-known, those patients who have apparently, an acute or florid onset of schizophrenia are admitted to a psychiatric hospital sooner than those cases having a gradual, insidious onset. Naturally, the therapy should be started before deterioration (irreversible functional changes) has set in. In the 110 cases treated by v. Meduna, 96 per cent of those cases who underwent therapy in the first year of their illness improved; on the other hand, less than 8 per cent of those whose symptoms had extended over three years improved. In our series, two out of three of the 20 cases treated showed improvement although they were over three years in duration, and of the 13 cases under one year in duration ten showed improvement.

Another question that arises is that of the probability of spontaneous remissions or improvements. A conservative estimate of this factor is that at the most, 40 per cent of all schizophrenics will improve in time. By this procedure, the percentage rises considerably above this figure. Furthermore, the course of schizophrenia cannot be predicted; it is impossible to state which particular case will improve and which one will not. The presentation

of the irritative therapy is brought forth with the idea in mind that it is possible to influence the schizophrenic process in a significant manner, and that actual remissive changes may be brought about by bio-therapeutic means.

The exact *modus operandi* of this therapy is as yet unknown. However, theories, as always, may well be propounded. The action of the convulsant drugs is essentially that of irritants to the central nervous system, as witnessed by the powerful psychomotor upheavals, toxic deliriform states and convulsive reactions, when large doses are administered. The action of the alkalinization is that of increasing the irritative background so that tolerance to the convulsant drugs is lowered and the action of the latter made more rapid. As an increment to the theories of v. Meduna, we postulate the possibility of a chemical detoxifying process, because the drugs are foreign to the body, and when given in large doses, may in the process of elimination, bring about chemical union and metabolism of fixed or cell-bound toxic agents that will be eliminated from the body in combination with the drug. v. Meduna mentioned the theory that there occurs in this induced epileptic state a "change in the milieu of the schizophrenic organism—chemically, metabolically or hematologically—that brings about an unfavorable background for the progress of the schizophrenic process." From our observation, we feel that the psychomotor upheavals during the convulsive state, and the prolonged psychomotor activity under the irritative régime indicate changes in the functional barriers discussed in the beginning of this paper. Thus a facilitation of the function of proper thought pathways which heretofore had been clouded or blocked by theoretical barriers to proper nutritional assimilation or utilization is brought about. Whether or not it is essential to produce the violent convulsive responses to bring about remissive changes in the schizophrenic disease process we cannot be certain. Perhaps if the central nervous system were to be irritated by more modifications of this procedure so that the therapy could be carried on over a little longer period of time, improvements could still be obtained. Further work is being carried on with this therapy by the author with the ultimate purpose of changing the long term institutional treatment of schizophrenia to one of much shorter duration and, as seems possible, to extramural practise.

Summary and Conclusions.

1. A recently developed method of treatment of schizophrenia along bio-therapeutic lines was presented. The technique and rationale of the irritative therapy modifying the procedure previously reported by v. Meduna was described.

2. Twenty cases of schizophrenia of various types and durations were treated. Remissive changes or improvements sufficient to allow release were established in 15 cases. Of these 15 cases, two had rapid relapses which could reasonably be attributed to insufficient treatment. Two cases showed some improvement, and three cases remained unimproved.

3. It is concluded as far as possible from this small series, that the irritative therapy of schizophrenia offers hopeful possibilities for the production of remissive changes in the disease process. It is, as yet, premature to indicate whether or not true remissions are taking place and more work is being done in this direction.

HERPES ZOSTER FOLLOWING LUMBAR PUNCTURE.*

A Case Report.

By H. R. CARTER, M. D., Palo Alto, Calif.

While it might be assumed that herpes zoster, as a sequel to trauma, might occasionally follow the procedure of lumbar puncture, a review of medical literature on herpes sinces 1810 fails to show any report of such an occurrence. The case here recorded is therefore of some clinical interest, although it is regretted that very little can be offered as to the etiology or pathogenesis.

R. S., an American aged 37 years, was admitted to the Veterans' Administration Facility February 3, 1937, in an intoxicated condition. The history shows that two weeks prior to admission, because his girl friend refused to marry him, he became depressed and drank whiskey excessively until admission.

Examination showed a thin adult male; fairly well nourished and well developed; blond hair, blue eyes, clear white skin; weight 144 pounds, height 71 inches. Eyes showed hyperopia, O. D. and hyperopic astigmatism, O. S. Ears showed the left tympanic membrane retracted; bone conduction reduced one-third, but still greater than air conduction. Both ears revealed whispered voice only for a distance of 6 inches, and spoken voice 8 feet. Absent tonsils, chronic gingivitis and dental caries. Pulse rate 110, temperature 37 deg. C., respirations 20. Blood pressure 140/90. Heart and lungs reveal no gross abnormality.

Neurological examination revealed the visual fields of both eyes slightly reduced. Optic disc on the left more pale than the right, retinal vessels normal. Pupils react poorly to light; no reaction to accommodation. Station and gait slight ataxia. Deep reflexes—biceps, triceps, brachials, costals and jaw moderately hyperactive, bilateral and equal. Patellar and Achilles absent billaterally. Superficial reflexes, epigastric, abdominal, cremasteric, all normal, bilaterally equal. Plantar reflex sluggish. Coarse tremor of extremities. Thermal and tactile sensation normal.

Mentally, confused, disoriented; active auditory hallucinations; depressed and says he wants to kill himself, "I have a terrible disease, cancer, or tuberculosis; people watch me on the street; oriental dope is injected into me through the walls." Emotional instability, crying for hours; poor judgment, impaired memory, no insight.

---

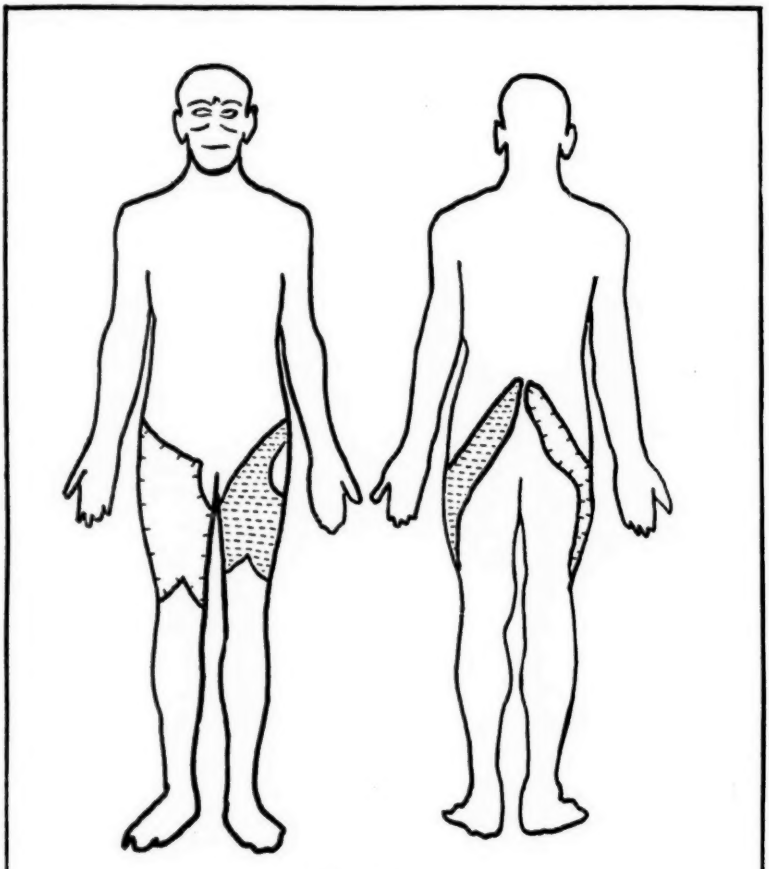
* From the Department of Neuropsychiatry, Veterans Administration Facility, Palo Alto, Calif.

Laboratory reports: urine, specific gravity 1.020, no albumin, no sugar, no casts in centrifuged specimen. Stool findings all normal. Red blood count, 4,760,000; hemoglobin 90 per cent; white blood cells 7,000; blood Wassermann 25 per cent positive.

Roentgenological examination showed slight calcification of pineal body; nasal accessory sinuses clear; small calcified nodule in right lung field; lumbar spine no pathology. Electrocardiogram showed cardiac rate 110, Q wave in all three leads. Basal metabolic rates, plus 3, and plus 6.

Treatment consisted of routine hospital care, light food, bed rest, together with small doses of sodium amytal by mouth. After one week, oriented; mental confusion, auditory hallucinations, and depression gradually left him. He laughed at the idea of killing himself. The blood Wassermann was repeated and showed a 25 per cent positive. Patient feeling fine and wanted to go home.

On March 2, 1937, some difficulty in passing the spinal needle in the intervertebral space of the third and fourth lumbar vertebræ, during which times the patient complained of pain despite the injection of procaine. Finally, the puncture was accomplished and a clear fluid was obtained, under 8 mm. of mercury pressure; cell count of 16, no red blood cells, trace of globulin, total protein of 62.4. Wassermann on 0.1 cc. of fluid 50 per cent, on 0.3 cc. 100 per cent. Colloidal gold curve 2254441100. Queckenstedt test normal.



Following this puncture the patient remained in bed for the next five days, having a headache. On the sixth day, he felt well, so walked about the ward.

Onset occurred on the eighth day, with a severe pain in the lumbar area. He was given infra red, followed with methyl salicylate and massage to the lumbar area. This pain continued in severity despite moderate doses of salicylates and codein. After 18 hours a fine erythematous maculo-papular eruption appeared on the left lumbar area and left buttock. On the ninth day the skin lesion spread down the lateral aspect of the thigh and anteriorly on the left leg. On this anterior surface the eruption extended from the inguinal ligament down to the lower third of the thigh. On the eleventh day, large vesicles appeared and the skin lesion was completely developed. The area involved is supplied by the posterior divisions of the first, second and third lumbar nerves, and the anterior divisions, namely, anterior femoral cutaneous, lateral femoral cutaneous, lumboinguinal and ilioinguinal nerves. Fig. 1 shows, on the left side, the distribution of the herpetic lesion and on the right side the distribution of the cutaneous nerve supply of these nerves.

Neurological examination revealed patellar reflexes absent. Cremasteric and abdominal reflexes bilaterally equal and normal. Plantar reflexes sluggish. Tactile sensation showed hyperesthesia over the anterior and lateral surface of the left leg down to the knee; and posteriorly over the left buttock upwards to the lumbar area. This area of hyperesthesia extended beyond the area of the herpetic lesion. Over this area there was no change to thermal sensation. On the right lumbar area and right leg there was no change from the normal in tactile and thermal sensation. Temperature 37 deg. C., pulse 100, respiration 18. White blood count 10,200, polymorphonuclears 75 per cent,

lymphocytes 18 per cent, eosinophiles 1 per cent, large mononuclears 4 per cent, and transitionals 2 per cent. All findings were normal in the urinalysis.

Treatment consisted of sodium iodide grams 1, intravenously on the ninth,

eleventh and thirteenth days. Roentgenotherapy consisted of 40 milliampere minutes, at 190 kilovolts, filtered 5 mm. of copper, at a distance of 70 cm., covering an area of 18 by 9 cm. over the site of lumbar puncture upwards to the twelfth thoracic vertebra. This was given on the tenth, twelfth and

fourteenth days. After the second roentgen ray exposure, the pain completely left the patient. In one week the herpetic lesion rapidly faded away and there were no residuals of pain or discomfort.

COMMENT.

This case of herpes zoster is not the essential type which is thought to be due to a virus similar to that of chicken pox; as there were no constitutional symptoms of fever, chills or tachycardia. The pain was the only symptom present in this case and is characteristic of secondary herpes zoster, such as due to syphilis, Pott's disease, spinal tumors, trauma, arsenic poisoning, etc. At no time in the patient's life history has he ever had any antiluetic or arsenical therapy for syphilis. The roentgenographic study of the lumbar spine and the negative Queckenstedt test rule out Pott's disease and spinal tumor. With these points in mind it must be concluded that the case here presented is a rare one in which direct trauma resulted in a herpetic lesion.

The chief evidence of the focus of the lesion shows the disturbance to have been in the somatic sensory component with some involvement of the splanchnic motor component, while the lesion itself was irritative in nature. The distribution of the cutaneous lesions showed that the pathological process was a disturbance of segmental function limited to dermatomic areas of the left side supplied by the first, second and third lumbar segments, involving alike the anterior and posterior dermatomic divisions. This localization provides two alternatives; first, in the peripheral nerves, including the first, second and third lumbar nerves; or, second, in the dorsal root ganglia corresponding to these nerves. As a rule, peripheral nerve lesions give sensory changes confined to the anterior dermatomic divisions. Here both anterior and posterior dermatomic divisions were implicated, which is the case of dorsal root ganglion involvement as well as in the dorsal root lesion.

The posterior root ganglion lie deeply protected by bone in the intervertebral foramen, it is unlikely in ordinary lumbar puncture technique that any trauma could occur directly to the ganglion. But the dorsal roots are somewhat fixed as they emerge from the meningeal membranes, so could be traumatized. Such trauma could produce an irritation which could travel to the dorsal root ganglion and up to the intersegmental neurones in the column of Clark. In

the posterior funiculus, this traumatic disturbance could spread by the intersegmental fibers to the closely neighboring dorsal roots of the second and first lumbar segments.

It cannot be stated definitely that no low grade infection, due to a virus, was added to the trauma. But it is thought to be unlikely as there were no signs of infection, such as fever, chills and tachycardia. The very short duration of the herpetic symptoms would indicate that infection was absent.

It may be said that the appearance of herpes zoster following lumbar puncture in this case is merely a coincidence, as it might be argued that the herpes is of luetic origin and would have occurred had the puncture never been made. This is possible, but the fact that the herpes followed the trauma of lumbar puncture and is so closely related to the lumbar nerves at the site of puncture, makes it difficult to believe it to be merely a coincidence.

It may be stated that the lumbar puncture facilitated the development of the herpes zoster as a luetic manifestation. Thus the herpes was due to the released luetic process rather than the trauma. But if it were a luetic herpes, it would have had a longer duration than one week, since no antiluetic therapy was given the patient. As it could hardly be expected that sodium iodide or roentgen therapy would be curative in a pure traumatic lesion, it is probable that the treatment had nothing to do with the short duration of the disease. Thus we may conclude that the short duration of the herpes was due to a mild irritative trauma of the dorsal roots rather than to any other process.

CONCLUSIONS.

Trauma can produce herpes zoster; and, as shown in this case, it can be produced where a spinal needle was passed with difficulty. This trauma occurred between the third and fourth vertebræ, where the dorsal roots of the left third lumbar nerve emerge from the meningeal membranes and descend downward and lateralward into the intervertebral foramen, wherein lies the dorsal root ganglion. This traumatic irritative disturbance was transmitted down to the dorsal root ganglion, and upwards to the intersegmental neurones in the cord to the level of the first lumbar segment. Thus the second, and first dorsal root ganglion exhibited this irritative disturbance; resulting in herpes zoster in the cutaneous distribution of these nerves in their dermatomic areas.

SUMMARY.

The case of a white adult male suffering from herpes zoster following lumbar puncture is reported. The herpetic eruption developed eight days following the trauma of lumbar puncture. The herpes zoster cleared up completely after one week of described treatment. An explanation of the neurological basis of the herpes zoster has been submitted. This is a rare condition considering the millions of lumbar punctures routinely done, in which no mention has ever been made of such an occurrence.

PRESENT CRISIS IN SOCIAL RELATIONSHIPS.*

By SAMUEL W. HARTWELL, M. D., Buffalo, N. Y.

Professions, the same as nations, have critical periods in their history. The psychiatric profession is at one of the cross roads. Certain decisions are made at such times that affect for long periods the direction and development of the profession. Our situation now is a close parallel of one that confronted the medical profession about 30 years ago when a general interest in public health and hygiene manifested itself. We all know how the profession, by being slow in recognizing the importance of this movement and accepting leadership in it, failed in a considerable measure to control and command this great field which we now recognize as being of equal importance socially and to the individual as is the treatment of disease. Today there is the same, or even greater general interest, in mental health and mental hygiene in their broadest meaning as there was in public health and personal hygiene, say 30 years ago. Now, as then, there are members of the profession who say, "This is our field; we must develop it slowly, and when we are ready we will let the public know what we have learned, and teach them to apply our principles."

Fifty per cent of all the people who present themselves to physicians for treatment have a mental illness, mental conflicts, or a mental history that easily may lead to a neurosis or psychosis. While the majority of these sick people do not come to physicians for mental treatment, many of them now do, and most of them are willing and anxious to receive help for their mental ills or poor psychic adjustments. Many of these people will become mentally ill in some degree if they are not given some kind of help.

A great majority of the physicians who treat these patients have had, either in medical school or in other ways, almost no formal training in the early diagnosis or treatment of mental illnesses, mental abnormalities or maladjustments, and only perfunctory train-

* Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

ing in fundamental psychiatry. Less than 2 per cent of the physicians in the United States and Canada are psychiatrists. Fifty per cent of all the sick people in these two countries who are hospitalized, are in mental hospitals or mental institutions and these, of course, occupy the time of almost all of the small number of psychiatrists who are trained and experienced in the care and treatment of this most unfortunate group of sick people.

Thirty years ago psychiatry began to move forward more rapidly. Some increased success in the treatment of the neurotic and even the psychotic patient was reported. A beginning was made in the understanding of the cause of mental disease. The very important fact that mental disease is not of sudden origin was established. These beginnings threw a dim light on some of the great *social* problems as well as on the problem of mental disease itself.

Relationships of mental disease to delinquency and crime were suggested. Legislators and courts became interested in psychiatry.

The concept of intelligence as a faculty of man that could be measured and better understood and utilized to maintain, and even to regain, mental health, happiness and normalcy, as well as a tool that could be used to help him make his living was established. Educators became interested in psychiatry.

Psychiatrists commenced to talk about group neurosis, national paranoia, and to explain group attitudes and behavior in psychologic ways that seemed logical. Sociology and politics became interested in psychiatry.

The psychiatrists commenced to see the tremendous importance to the individual of the efforts he makes in his childhood and maturity to understand his confusing world and his mysterious self. The relationships between these efforts and mental health were pointed out. Religion was seen as man's most important concrete manifestation of this psychic activity. The church and the clergyman became interested in psychiatry.

Thirty years ago when the ideas originating largely in psychiatry, but coming from other fields as well, began to crystallize into what is now usually called "mental hygiene," there were already many groups of people approaching the problem of helping others less fortunate than themselves to find a better adjustment to life. Some of them already called themselves social workers. Others had other

names. All were floundering in their theories and practices and largely at a loss to explain their successes or failures. They attempted to help or change individuals. There was no agreement as to what kind of change should be sought for, or what kind of help was truly helpful. When the psychiatric study of the individual was established as a dynamic constructive approach to an understanding and solution of his problems, it not only offered these people new hope for better standards and results, but furnished them a common meeting ground. Real integration and organization of social work within itself has come about most largely through the gradual development and practice of social psychiatry and mental hygiene. Of course, the social worker became interested in psychiatry and, we must all admit, has made no insignificant contribution to modern psychiatry itself.

Many of the leaders in all of these fields allied to medicine, for allied they are, even though we as a medical profession sometimes try to avoid a recognition of our close relationships, were and are conservative and yet hopeful as to how much or how rapidly the psychiatrists might bring them help with their problems. But conservatism was difficult. Psychiatry developed most rapidly during the years when tremendously important scientific discoveries were being made. Nearly everyone believed that science could be relied on to solve every problem. When Healy reported that a few bad boys who had solved their mental conflicts, were no longer delinquent, it was immediately assumed by many that the solution of the problem of crime had been found. When Goddard reported that a few unhappy, maladjusted, feeble minded patients had found, through the education of their hands, a happiness, many assumed that special classes and special training would solve the social problem of the feeble minded. When Freud reported that a few obsessional neurotics had found surcease from their mental torment through psychoanalysis, it was assumed by many people that the problem of mental disease was about to be solved.

Then came the war with all its material and psychic implications. Governments and social systems toppled and fell. Our own, we felt, was threatened. Religion was suddenly neglected or rejected by many individuals as well as entire nations. Religious creeds were changed. New ones sprang up. The nations of the world found

themselves profoundly in need of help, and millions of individuals came to realize that *they* needed help. This condition still prevails and now the whole world is turning to psychiatry. In this country particularly, there will be *no long waiting* for us as a professional group to slowly solve our problems of integration within ourselves or with the new groups or professions more or less related to us. The time has come when we can no longer work on these problems slowly. We must make some decisions or the decisions will be made for us.

The Committee on Social Relationships of this society has, during the past few years devoted much time and study to these problems. It is highly important that this society as a group, and the members as individuals, should become aware of these situations and problems. We must inform ourselves about them to the end that we as a profession may act wisely and well in making decisions that will finally determine the position our profession will hold. I propose to discuss informally some of the more important.

Some 15 or 20 years ago, preventive psychiatry and early psychotherapy had their first formulation. The idea that human unhappiness and maladjustment, both social and personal, had some very direct relationship to mental disease was formulated and accepted. The understanding of this relationship in all its ramifications brought a new understanding of mental health as something that might be planned for in the child's experiences, might be maintained in adulthood, and may even be regained if lost. Everyone assumed that this new and enlarged approach belonged to psychiatry which had, of course, had the major part in describing the principles on which this new thought is based. But the idea was popularized and was grasped by a confused and faltering world, and especially by those people and agencies and institutions whose field of effort was helping people get out and keep out of trouble with themselves and others. It was over-popularized and over-sold. Too much was promised. False hope was held out. Psychiatry was not accountable for all of this, but we certainly were not blameless. But despite the inevitable disappointments, the idea and practice of mental hygiene remain and grow and become more constructive, useful and more health bringing as our mistakes in theoretical thinking are corrected and conservatism again comes into its own as it always has and

always will in all branches of medicine. The question now is, and it is a very important question for the psychiatric profession: what is to be our part in this great movement of mental health? Is psychiatry to maintain its leadership that will be more conservative, more productive, and at least for the next generation, more useful than any other leadership that may develop or can develop within the present generation?

Let us to take stock and see where we now stand. Where are we now? A hundred thousand school teachers and principals are trying to put into practice the principles and sometimes the theories before they become principles of mental hygiene. Within 10 years from today five hundred thousand teachers, all of them in fact, will be trying to mold all of the children of our great school system into patterns of mental health. They are, and they will be, thus trying to prevent mental disease as well as trying to make our children develop into happy and well adjusted adults. This will happen whether psychiatrists think it will or not, and whether psychiatry takes the lead or not.

Where are we now? Approximately one-fourth of all people, both children and adults, who are accused of crime in this country are being thought about and studied, and sometimes treated in terms of mental hygiene. Within 10 years, if present trends continue, as they will—witness our new social security laws—a major part of all our criminals will be so studied and treated. Again, this will happen whether we as a professional group think it should or not, and whether or not we accept the leadership in the training and supervision of the thousands who are going to carry it on.

Where are we now? Conservatively one million fathers and mothers are trying their best, in one way or another, to inform themselves so that they may utilize the principles that mental hygiene is suggesting as practical ways of bringing up their children to the end that they may have normal mental lives and good personality adaptations. We all agree that these efforts will have a profound effect for good or ill. Who is to establish these principles and who is to teach them? We know that only a small part of such teaching that is being given these anxious parents is being done by properly trained and conservative psychiatrists. Psychiatry will never solve this problem by condemning the practice of thoughtless,

careless, popularized newspaper type of psychiatric and mental hygiene teaching, but they still have the opportunity to effectively combat it by doing it themselves. But in this matter and with others of the problems that we are now facing we must have the help of the general medical profession. And that brings us to another of our problems of social relationships.

And where are we now? This year 16,000,000 people will consult physicians of the United States and Canada. One-half of these will need mental help of some kind. Because of increased dissemination of knowledge concerning psychological facts and fancies, but more because of the great and increasing need for this kind of help in this confusing world, there will be more of these 8,000,000 people who will expect the physician to be the psychotherapist or to recognize his need for someone who can help him, than there was last year. Next year there will be more than ever who will recognize this need. Are physicians ready to supply it? This audience knows the answer to this question. Are we interested in the fact that they are not ready? To say we are not, is to say in effect that psychiatry as a profession is either unwilling or unable to accept as part of our professional field the great field of mental health. Is it in part our fault that psychiatry does not have its proper place in the medical profession? Within ourselves we are thoroughly agreed that psychiatry is a part of medicine, and that the practice of the art of mental healing belongs to us as members of the medical profession. But is the medical profession as thoroughly convinced that psychiatry is a part of medicine, as is the psychiatrist? Are they as disturbed as we would wish when they find some nonmedically trained person practicing psychiatry? Is it not true that many physicians thoroughly competent to treat physical diseases will give inexpert advice to mentally disturbed patients or will belittle their symptoms, or perhaps suggest some type of unethical treatment, not recognizing that the psychiatrist is trained to deal expertly with the situation? Is it not true that many physicians are even proud of the fact that they have no knowledge about, or interest in, psychiatry? In short, while we consider ourselves doctors, are we in truth considered such by all the members of the medical profession?

The question of psychiatric education in the medical schools is the most dynamic question that faces the medical profession today.

Unless the next generation of physicians are trained to help the psychiatrist in the early diagnosis and in the treatment of the simpler and early conditions to the same degree that the general practitioner directs hygienic measures and treats the less complicated disease processes that, becoming serious, are the problems of the specialist, the psychiatrists will no more be able to carry on all the treatment and education that will be demanded of them within the next few years, than could the oral surgeons extract all the temporary teeth of all the children in the United States. In the bringing about of the changes that must occur in the psychiatric teaching in our medical schools, those psychiatrists who see the need of psychiatry accepting this new and tremendously greater responsibility, must take leadership.

Nearly all psychiatrists are commencing to recognize the same fact that the general medical profession finally recognized 50 years ago, after a great deal of resistance when the training of nurses in the techniques of the art and science of medicine was under discussion. We now know that we must have trained people to help us, and that we can have them and still maintain control and leadership in our specialty in medicine, as has the doctor maintained his leadership in physical medicine, despite the fact that there are many times more nurses and technicians who are trained in medical sciences than there are physicians. We cannot get along without social workers and they bring us problems.

Two important facts should loom large in our consideration. First, the tremendous increase in the number of people who, in the various and diverse fields of social work, are being trained in social psychiatry and mental hygiene, and in the rapid augmentation of the importance of the positions these social workers hold. And they nearly all bring the "psychiatric approach" to their tasks. Social workers are directors of vast government projects, they head private agencies and institutions of social welfare. They hold important political and government positions. They are law makers, expert advisors and cabinet members. They make laws and determine policies of the greatest importance to the mental welfare of great numbers of people. The psychiatric profession is represented almost not at all in these same fields. Second, the rapid change that is occurring in the aims and techniques of social work. Technically

they call it "a new emphasis in case work." To all intents and purposes it is practicing psychiatry, elementary psychiatry perhaps, but psychiatry none the less. In only a very small way, and in isolated instances are these social workers attempting to infringe on our professional field. But their area of activity is being constantly enlarged because more and more it becomes evident that they cannot choose the kind of case work they must do. If they do not include in their study and treatment an approach to the mental life of their clients, they will fail in results, and they will lose their jobs.

Psychiatry was not ready for this rapid growth. Had the general medical profession been trained and prepared to help us with the problem, we would not be as overwhelmed as we now are. In many cities of from 25 to 100,000 population there will be say, 50 social workers in family agencies, public school systems, juvenile and adult courts and in religious agencies who have had formal, and often very good training in social psychiatry and mental hygiene who need, and are desperately looking for consultation and advice from the psychiatrist. And in these same cities there will often be not one single psychiatrist who sees their need and has time and the training necessary for him to supply it, even in a very small way with the more serious cases. Of these 50 workers it would be a safe guess to say that 48 have strong disinclinations to take the responsibility in psychiatric diagnosis and psychotherapy that their work demands.

An even more serious fact is that the demand for good teaching of social psychiatry and mental hygiene in the schools where these workers are being trained cannot at present be met. Also a part of their training must necessarily be field training. It has been assumed, and probably correctly, that the best place for such training, at least the basic part of it, is the mental hospital. But many mental hospitals have been slow to enlarge their personnel and expand their ideas and practices in social psychiatry sufficiently to supply this need for field training.

The result of these various situations is that not only is the social worker handicapped when he or she seeks leadership and supervision from the psychiatrist, or from the physician who is the next person to whom they turn, but they are also handicapped by being trained often, both didactically and in practice, by nonpsychiatric and even nonmedical personnel.

The stage is set for some change. There is only the remotest possibility that the change will be a decrease in demand for social workers. Modern social work is producing results. The results are not as good as they would be were the psychiatric profession ready and equipped to keep pace with its rapid development. The social worker needs help. His job is too detailed and likewise too important for him to ever consider himself self-sufficient. He will need definite help in his more serious cases. He needs advice and supervision in his simpler ones. He needs supervision in his duties as an educator and leader in community thought, planning and training in the field of mental health and social psychotherapy. One of two things will happen: either psychiatry will supply his needs or a new profession will develop. What can we do about it now?

First, we can admit our inadequacy at the moment to handle the situation efficaciously.

Second, we can train more young doctors in social psychiatry.

Third, the institutional group can enlarge their activities to include more out-patient service, better supervision and treatment of the people who have been mentally sick and in institutions, or who are in danger of becoming institutionalized and thus provide better training for social workers, and better training for their junior staff in using social workers to help them in the practice of psychiatry.

Fourth, psychiatrists can give of their time and attention to community and social planning, and lend a conservative note to over-enthusiastic boards of education, executive committees of social agencies and religious groups who are trying to develop mental hygiene resources when there is little or no possibility of their being able to do so.

Fifth, we can provide opportunities for doctors who are now practicing medicine, and there are many of them, who want information and training in the field of psychiatry. The great body of medical practitioners regret the fact that they do not know more about the recognition and treatment of the milder forms of mental disease, and they regret the fact that they seem no longer to be intimately in the situation as a physician when their patient becomes mentally sick. More good books written by psychiatrists for the general practitioner are needed. Medical societies are always open

for papers on psychiatric aspects of medicine, especially if these carry concrete suggestions that the physician may use. Medical journals can be encouraged to publish such articles, and doctors encouraged to read them. We must frankly admit to the general medical profession that we need their help and, failing to get it, we must needs accept the more limited view of psychiatry as a profession dealing with the diagnosis, care and treatment of the seriously mentally ill.

Sixth, and this in my opinion, is the true attack, we can teach medical students psychiatry in such a way that it will be considered a basic part of medicine. Medical students are not different from other human beings. It is only the ultra-scientific approach to the teaching of medicine that has made it possible for a generation of physicians to approach in a detailed, often very successful way, the treatment of the diseases and dysfunctions of the various organs and systems of their patients with almost complete disregard for the patient as an individual. It is the fault of the training of the medical student that when the average physician is approached by law-makers, executives or social planners, he is unable to add that note of understanding, or give the concrete advice that is needed. We, as a medical profession, have a great birth-right in leadership in the field of human relations. We have been bargaining this away needlessly. Very definitely the trend in medical education is toward the teaching of psychiatry in its broader aspects. Our society and our profession must endorse and insist on this in every way possible if we are to retain our leadership in the field of social endeavor and social change.

And, finally, I should like to mention very briefly the perhaps most significant and often entirely overlooked situation now awaiting our action. In this country and in many other countries profound and rapid changes in social relationships are occurring. These are being reflected, and often seemingly brought about, by new laws. In the United States within the past four years there have been passed literally hundreds of laws, both federal and state, that carry a direct or indirect psychiatric implication. The execution of these laws is creating a demand for psychiatrists in new jobs and new set-ups. There are few psychiatrists who have had proper training and few opportunities for young physicians to get

the proper training for these jobs. Some of them are being filled by nonmedical people. In many states laws governing mental examination of criminals and defectives are being changed so that the examination must be made by a truly qualified psychiatrist. Rapid social changes are producing personal tensions in large groups of our citizens, thus directly increasing the number of people who need therapy or institutionalization. Perhaps the most important point of all in the immediate present is this: law makers and executives are turning to psychiatrists for advice as to how the laws should be written and enforced, for predictions as to what effect these new plans will have on the psychic adjustment of the citizens. In one way or another, and after few or many trials, successful plans for social welfare are going to be formulated. Are we as a profession to have our just part in them? All these things bring a demand for a broader kind of thinking on the psychiatrist's part, and we, as members of the profession, should get the concept of psychiatry as a broad and basic profession, if we are to function in our proper place in years to come. For examples:

Will psychiatry have any part in the formulating of plans that will lead to the solution of the great problem of decreasing the number of children predestined to a life of unhappiness, disease and failure that will be born?

Shall we have anything to say as to how we as a nation may lay plans to prevent sudden and catastrophic changes in forms of government?

If science and religion are to find a common meeting ground and religion again have, as it has in the past, a profoundly helpful part in most people's lives, are we to help find this meeting ground?

If people are at length to find some other value in life than wealth and possessions that will carry them through times of financial depression without injury to their personality, are we to have a part in this?

If war is finally to be no longer a part of human behavior, will we have any part in bringing this about?

Now, all of these problems originate in the mental life of human beings. We are doctors of the mind. Let us assume our responsibility.

DISCUSSION.

DR. GEORGE S. STEVENSON (New York).—Most of the sessions that have been held under this program might be termed scientific sessions. This one is a session of propaganda or promotion. I think we have to come to a true appreciation of the relationship between a scientific effort and a promotional effort.

All the points that Dr. Hartwell has brought out are worthy of continued consideration. They are realistic; they are capable of achievement.

I went into the classroom of a professor of psychiatry who was teaching his first-year medical students. He was putting before them the picture of a community, putting before them the fact that people are, after all, integrated beings, that they were going to have to deal with a part of that integrated person, but there were other parts of the community that were dealing with other parts of him, and so he was presenting the community to these students so that they would know that with which they would have to cooperate, and know the functions of each of these, educational, judicial, social service, theological and other aspects of the community.

I might say that this professor, who was Dr. Hartwell, then went on to discuss the county medical society as a community agency, the things that made it resistant to progress, the things that made it defensive, the things that made it keep aloof from those that it should be cooperating with, the things that made it steer clear of the realities of the social problems of people and refuse to do what it could to attack these social problems, merely opposing those who went ahead with extreme proposals for dealing with them.

I think that presentation to those first-year medical students is an example of the reality of the thing that Dr. Hartwell is dealing with.

In May, 1937, that is this morning Ruggles and Fitzpatrick presented a paper before this Association, calling attention to the fact that the hospital is a community agency. It has suffered isolation because it has been withdrawn from its community in order to achieve a higher level of professional service, and in being drawn from its community, it has often lost its grasp on the community, and the community has lost grasp on it. It is the recapturing of that relationship that Dr. Hartwell has in mind, the recapturing of it sufficiently so that when the government comes along with a local project which needs psychiatric advice, they can say, "Well, here are a group of psychiatrists who know so much about our community, who are so interested in the problems that people are faced with in this community that we can fully depend upon their participation.

Dr. Hartwell also spoke about the question of leadership, as also did Dr. Ruggles and Dr. Fitzpatrick. I don't have a great deal of fear that leadership will pass from psychiatry to other hands when it is leadership concerned with psychiatric problems, because there is necessary to that leadership a certain foundation of technical appropriation. I do have fear that the progress may be muddied somewhat, and delayed a great deal by

the weakness of psychiatric leadership, and distorted through the interference of political activities that come in through the gaps permitted by that weakness.

I have no fear, also, because I know that social work has such an immense job in its own central point of activity that it isn't going to be able to go over and do a lot of psychiatry. They may talk about it, but if you actually go into it, that represents an interest in a border zone. They are very heavily preoccupied with another type of work, and they are demanding of psychiatry certain specific things which Dr. Hartwell has pointed to. They want help; they are afraid of some of the things that they are running into. They want to be able to take a record to a psychiatrist and say to him, "Look this over; see if you think this patient ought to be sent to you," and if he says, "I won't look it over unless I can see the person himself or herself," something is lost. Or a little further on he will say, "Can you give me consultation on this case?" or, "Can you hold a conference for our staff that will help in their development and help in the mutual relationship of these two professional activities?" or, "Here is a patient, obviously a psychiatric case in this home, disrupting the whole life experience of the children in that home. Does the patient have to commit some crime before he can get psychiatric advice and be taken to a hospital? What can you do to provide us with family physicians who are psychiatrically oriented?"

They are all problems that are being put up to psychiatrists, because the dealing with people demands of social workers that they face their problems. They are passing some of them on to us.

Our Government has WPA programs which put up buildings. We have to be very careful that those buildings do not crystallize for fifty years to come a situation of 1936 and '37, because they are hard to move. Then we have an entirely different activity under the Social Security Act, which we might speak of as functional, in which the Government is going into communities and is saying, "We will participate if your standard of activity is high enough," and then they have to go to psychiatrists and say, "What is the standard of activity in this field that we must demand of those communities?"

That is another thing that is going to put a requirement upon psychiatrists particularly in mental hospitals, because they are the only generally distributed psychiatric activity, to cooperate with the Government in providing a high type of psychiatric service, and in moving up its front line so that the rest of the social program can also move ahead.

DR. SAMUEL HARTWELL (Closing) (Buffalo, N. Y.).—It seems to me one of the things we should think most about is to keep mental hygiene and the state hospitals, extra-mural and intramural psychiatry close together. I practiced medicine for fifteen years. I was in a state hospital for five. I have been in extra-mural psychiatry for about the same length of time, and they belong together. I think perhaps the state hospital group have

neglected sometimes the opportunities that they have had to enter the field of mental hygiene. There are many reasons why they should do this. They should do this first, I think, to keep themselves alive, to keep themselves confident, to have enthusiasm for their work and faith in it. Secondly, I think they should be together with the extra-mural group so that they may keep a check on the extra-mural group. No doubt we get too enthusiastic at times. That is another reason why we belong together. We belong together because we are working to the same end, mental health.

THE EFFECT OF THE STIMULUS WORD USED UPON SCORES IN THE ASSOCIATION-MOTOR TEST.

By NEWELL C. KEPHART and H. MAX HOUTCHENS,
Iowa Child Welfare Research Station, State University of Iowa, Iowa City, Iowa.

During the past 30 years under the influence of the experiments of Jung,[4] Kent and Rosanoff,[5] Woodrow and Lowell,[7] *et al.*, the word association method has come to be well established in clinical psychology and psychiatry as an indicator of mental complexes. Recently A. R. Luria[6] has developed a refinement of this technique involving, in addition to the conventional indicators (verbal disturbance and disturbances of reaction time), disturbances of voluntary and involuntary movements of the hand. Experiments with this association-motor technique have been made by Luria,[6] Huston, Shakow and Erickson,[3] and by Barnacle, Ebaugh and Lemere.[1] The majority of the studies have made the assumption that the specific word used in the test calls up in the mind of the subject a specific complex with which it is associated and thus through this associational bond leads to a disturbance in the test. As a result of extensive testing of more or less normal individuals, the writers were led to believe that association might better be conceived of as a mental process and that disturbances in association tests might be indications of the amount of disturbance of this process, rather than rising from a specific situation which is presented to the subject's mind by the specific test word. It is this thesis which the present investigation will attempt to substantiate. In addition, evidence will be presented as to the presence and magnitude of practice effects in the association-motor technique.

The two lists of words most commonly used in association tests are those of Kent and Rosanoff and of Jung. Each is composed of 100 words. These lists were standardized in radically different ways. That of Kent and Rosanoff was an attempt to select a list composed as nearly as possible of "neutral" words while that of Jung is composed of a large number of "critical" words and few "neutral" words. If both of these lists were given to the same

subjects, one would expect a higher score on the Jung list (provided the hypothesis of a specific word calling up a specific response is correct) since, if this list contains more words "critical" to common complex situations, we should expect by chance to hit into a greater number of complexes in a group of subjects. If, however, the hypothesis advanced in this study is correct, we should expect the same average score regardless of the list used, since in this case the words used represent merely a sample of the functioning of the mental process regardless of the nature of the word, provided only it be a common word whose meaning is known to the subject. If this hypothesis is correct, any list of words of the same length chosen at random should give the same results.

The subjects were 50 boys from the State Juvenile Home at Toledo, Iowa.* These subjects ranged in chronological age from 12 to 18, in mental age (Binet) from 12 years, 8 months to 17 years, 3 months, and in IQ from 82 to 118. The mean chronological age was 15 years, 2 months; mean mental age, 14 years, 2 months; mean IQ, 96. This represents an unselected group except that a subject was required to have a mental age of 12 years or more.

The apparatus used by the writers consisted of a polygraph set-up which included an electro-magnet system for recording time between stimulus-response, and two tambour air systems for recording motor responses from pressure cups for each hand. The subject was seated comfortably with his arms at ease on a table in front of him. The preferred hand was so placed that the tips of the first and second fingers could be used to press on one of the pressure cups. The nonpreferred hand was likewise arranged so that the first and second fingers could rest passively on the other pressure cup. These cups were constructed so as to record the slightest pressure and tremor on the polygraph.

Four components of the association were thus recorded: reaction time, verbal response, voluntary motor response and involuntary motor response. In obtaining the total weighted score each disturbance of verbal response was multiplied by one, each disturbance of reaction time by 12, each disturbance of voluntary motor response by six, and each disturbance of involuntary motor re-

* The writers are grateful for the co-operation and assistance of Miss LaVere Smith, superintendent of the State Juvenile Home.

sponse by seven. The apparatus and scoring technique are the same as those used by Houtchens.[2] The reliability of scoring as reported by Houtchens is $.95 \pm .01$ on disturbances marked.

A standard procedure was strictly adhered to in administering the test to each subject. The factors involved in administration included putting the subject at ease and removing any apprehension toward the apparatus, using the same directions for explaining the procedure to each subject, and excluding any external disturbing factors from the scene of the experiment.

Each subject was tested twice, once with the Kent-Rosanoff list of words and once with the Jung list. The tests were given on two successive days. Since it was desired to separate the influence of practice effects from the influence of the list used, the group was divided into two parts, the order of the lists being alternated between the two. That is, one-half of the group was tested with the Kent-Rosanoff list the first day followed by the Jung list the second day and the other half was tested with the Jung list the first day followed by the Kent-Rosanoff list the second day. The tests were scored and the means and standard deviations for each of the four components computed in terms of frequency of disturbance, and the mean and standard deviation of the weighted total computed in terms of score units. These results are presented in Table 1.

In the first half of Table 2 are presented the differences which have to do with the factor of list differences. These three comparisons are those between the Jung list given first and the Kent-Rosanoff list given first, the Jung given second and the Kent-Rosanoff given second, all of the Jung scores combined and all of the Kent-Rosanoff scores combined. From Table 2 it will be seen that all of the differences are not in the same direction, ten being positive and five negative. The critical ratios vary from 0.00 to 2.23. Thus none of the differences are statistically significant. We, therefore, conclude that there is no difference between mean scores on the two lists.

Another method of testing for list differences was by correlation. The Jung lists were correlated with the Kent-Rosanoff lists yielding an r of .79. The split half reliability of this technique is .82. Thus it is seen that the correlation between the two lists approaches closely the reliability of the technique, indicating that

the substitution of a new word list does not change the placement of the individuals in the group significantly more than would a second administration of the same word list.

Further, 19 words were found which were identical in both lists. These 19 words were sorted out and separate scores computed on this basis for both lists. That is, a score was computed on these 19 words administered in the Jung list and another for the same 19 words administered in the Kent-Rosanoff list. These two scores correlated gave an r of $+.49$; corrected by the Spearman-Brown formula with $N=5$ to compensate for the length of the test, this becomes $+.83$. Thus it is seen that these words are representative of the list as a whole and aside from the shortening of the list present a reliability as administered equal to that of the test as a whole. Disturbances on these 19 words were plotted separately for the administrations in the Jung and the Kent-Rosanoff. Each item was then scored as a reversal or a nonreversal. Regardless of the type of disturbance, if the item showed a disturbance in one administration and not in the other, it was scored as a reversal; if no disturbances were marked for the item or if disturbances were marked in both administrations, it was scored as a nonreversal. If the first hypothesis here presented were true, and a specific word called up a specific conflict situation thus leading to a disturbance, the percentage of reversal would approximate 0 since the same word would call up the same situation again thus leading to disturbances in both administrations. Chance would be approximately 50 per cent. The average percentage of reversal found in this study was 42.9 per cent. This approximates chance much more closely than the value expected if this hypothesis were true.

From these data we conclude that the process of association represents a sample of the amount of mental disturbance rather than a specific conflict situation suggested by a specific stimulus word, and that the subject within the limits of the reliability of the technique and regardless of the word list used will show a given number of disturbances per 100 words. Thus the word list may be better thought of as a random sample of a process which is easily disorganized rather than as a list containing a given number of words "critical" to a given subject. This would indicate that the association-motor technique represents a good method of sampling the amount of mental disturbances at least for group purposes.

The second half of Table 2 presents those comparisons which have to do with the factor of practice effects. These are the Jung list administered first with the Jung list administered second, the Kent-Rosanoff list administered first with the Kent-Rosanoff list administered second, and the total of all first tests with the total of all second tests. From Table 2 it will be seen that all differences are positive but one. However, the critical ratios are all too low to admit of statistical reliability, ranging from 0.05 to 2.00. Since all the differences but one are in the same direction we conclude that there is a slight practice effect which is, however, too small to be significant.

CONCLUSIONS.

1. Within the limits of the group defined here and with fairly normal individuals, group scores on the association-motor test are independent of the word list used, provided the words are common in the language and their meaning is known to the subject.

2. With an interval of one day between testings there is a slight practice effect which is, however, too small to be statistically significant.

THE DISCLOSURE OF FOSTER-PARENTAGE TO A BOY.

Behavior Disorders and Other Psychological Problems Resulting.*

By SIDNEY TARACHOW, M. D., New York City.

The purpose of this communication is to present some of the readily ascertainable psychological problems incident to a child's learning that the persons he has always assumed to be his real parents are only foster parents. The examples presented are culled from an unselected group of 250 admissions to the New York State Training School for Boys. The formula followed by these cases is a fairly uniform one; an illegitimate child is deserted in infancy by its parents, and adopted by strangers who bring it up as a child of their own. At some later date in childhood, usually near early puberty, the truth is somehow revealed. The revelation may or may not be preceded by a preliminary period of doubt in the child's mind. Certain psychological events occur, the most characteristic behavior pattern resulting being desertion of the home. Specific problems are best discussed in direct relationship to the cases.

Case 1.—J. B. a colored boy of 14.

Family Background.—The mother came to Brooklyn from Virginia in 1921. As the result of illicit sexual relations, she became pregnant. Nothing is known about the father except that he deserted before the child was born. When the boy was two months old the mother boarded him out to the present foster mother. The mother saw the boy several times until he was eight months old, although she never showed any fondness for him. The mother then disappeared, and nothing definite has been known of her since. The foster mother is a negress with Indian blood on the maternal side. She was brought up as an orphan and was treated very cruelly in childhood. She married at 19, lived happily with her husband, and had four children. Three sons are living and married; one daughter lives at home and helps support the home by working in a laundry. Her husband died, and she remarried. About six years ago, the second husband became interested in another woman and

* From the Medical and Research Department, conducted by the New York Neurological Institute, at the New York State Training School for Boys, State School, Orange County, N. Y.

deserted, although he visits the home very occasionally and sometimes contributes to its support. The home is poverty stricken and unsanitary, though not on relief. There is a boarder. The foster mother is ill with heart disease and spends much time in bed.

Boy's Development.—The pregnancy and delivery of our subject were normal. He was breast fed until four months of age and then put on the bottle. He was a quiet baby and child who obeyed well, showed no aggressive tendencies, but had occasional fits of crying. Though the mother showed no affection, the foster parents did. He was always of a quiet disposition. He began school at six, and reached the fifth grade. His behavior and attitude in school were always satisfactory. He mingled poorly with other boys, was known as a "lone wolf," and his chief diversion was the movies. He suffered an injury to his spine at the age of eight, and was kept out of school for one year. During this time, the foster mother was very solicitous about his health. He suffered the usual childhood diseases and a tonsillectomy and appendectomy.

The Boy's Problem.—The boy was eight when the step-father deserted. This did not affect the behavior of the boy though the economic level of the family dropped then. When he was 12, the foster mother revealed to the boy what she knew of his parentage. Shortly after this, he began to desert home, be dishonest, steal small amounts of money from home, and was a truant from school. He was put on probation by the Children's Court, but violated probation by stealing some money from his foster mother. He was then committed to the New York State Training School for Boys.

Institutional Findings.—Examination disclosed no physical defects, except a spina bifida at the fifth lumbar vertebra shown by X-ray. He had an I. Q. of 90 and an E. Q. of 91, with an educational achievement of seventh grade work, two years ahead of his school placement. Interviews disclosed a friendly, mild-mannered boy. There were no signs of psychosis and no overt neurotic symptoms. He said that he first began to suspect that his parents were not his own when he was nine, but was not certain until his foster mother told him. He definitely stated that he began stealing after he learned this. He felt very resentful at not having been told something so important before. He often had fantasies of his real mother returning to claim him. Shortly before the first desertion, he suddenly got the idea that his foster parents didn't want him. He had no place to go, but he deserted.

Comment.—This boy demonstrates: (a) the preliminary period of uncertainty of parentage; (b) resentment at not having been previously informed of a fact of tremendous importance; (c) fantasies of the real mother coming to claim him; (d) onset of anti-social behavior after the disclosure; (e) onset of home desertions after the disclosure, the desertions being somewhat irrational, with no definite conscious purpose or place; (f) fantasies of the foster parents not wanting him, a belief definitely not justified by the foster parents' real attitude.

CASE 2.—R. W. a colored boy of 16:

Family Background.—The mother was a Virginia negress who became impregnated while on a visit to New York City. Nothing is known of the father. When the mother became aware of her pregnancy, she left home and went to Washington, D. C., without informing her parents of her real reason for doing so. She had no love for the child, and regarded it as the great mistake of her life. The mother took care of the child for the first 18 months, and then because of illness gave it to a sister who cared for it for one year. At the end of the year, it was given into the custody of the present foster mother, who assumed the rôle of mother. The boy looked upon these people as his real parents, and seems to have adjusted well. However, the foster father became ill with tuberculosis, the home was broken up, and the boy was sent at the age of six, back to the South to live with his grandparents. Here he stayed until he was nine. He developed a great attachment to his grandmother, learned how to cook, and spent much time playing with dolls. His real mother was at that time living in the same home with him, but he was told that she was his aunt. She died of tuberculosis when our subject was eight years old. It was during this time that it was hinted to him that the people he took to be his parents in New York City were not really so, but he never could feel certain. From that time on, he was always in some doubt and a good deal of anxiety, though he continued to look on the foster mother as mother. The usual terms of address were always "mother" and "son." At the age of nine he was sent back to New York to live with his "mother," who had remarried after the death of her first husband. Here he lived until his present difficulties began. The second husband was a kind, friendly man, a laborer, and always did his best to help him. The economic level of the home was not very high, but self-sustaining and clean.

Boy's Development.—Nothing is known of the pregnancy or delivery. He was bottle fed. At the age of three he had several convulsions, was treated in a hospital, and never suffered from convulsions thereafter. Even as a very young child, he was known to talk a great deal to himself. After the age of six, he would often describe having seen strange animals and talking with strange men. He was early interested in dramatics, acting, and would often improvise a stage in the loft of the barn. In New York, he did fairly well in school, received grades of B, and reached the eighth grade. He refused the company of either boys or girls, shunned athletics, was interested in dramatics and choir singing. He was known to do ballet dancing in the privacy of his own room when he felt he was alone in the house.

The Boy's Problem.—At about the age of 14 his foster parents began to have suspicions of homosexual activity on the part of the boy. He would be seen in the company of older men, would suddenly disappear for a few hours and return with several dollars, he was seen entering apartment houses in the company of men. He was decidedly effeminate in mannerisms, speech and tastes. His foster mother and father tried kindly argument and persuasion without avail in an attempt to direct him sexually. At the age of 15, syphilitic lesions were found in his mouth and rectum. Treatment was started. Shortly thereafter, he accidentally saw his birth certificate, and learned definitely that

the people he was living with were not his real parents. This was the proof of his suspicions and doubts, and was a terrible blow. The chief emotional feeling was one of resentment at having been deliberately misled. He became angry and hostile, but at the same time began to develop in a melodramatic way the ideas that he was a burden to his foster parents and that nobody wanted him. He often threatened suicide. One month later he ran away, was apprehended some days later and persistently deserted home four more times. He repeated each time that he was not going to stay at home and would continue to desert. He was then committed to the New York State Training School for Boys.

Institutional Findings.—Examination showed no system disease. A blood Wassermann was negative on four occasions. Neurological examination showed minimal scattered signs, probably the residue of an old inflammatory process in infancy. The I. Q. was 83. The E. Q. was 79 with a sixth grade educational achievement. Interviews disclosed an effeminate boy who was hostile and uncooperative. He refused to abide by the ordinary regulations. He mingled poorly with other boys, and sought out the company of another homosexual boy. Nothing unusual about his speech production. Emotionally he varied, often cheerful and happy, at other times dramatically depressed. He expressed an enormous self interest, had no interest in anybody else, stated he would never love anyone. Preferred to be alone. Felt that nobody liked him, and the moment any one balked him, they were at once labeled "enemies." He railed against the cruelty of his foster father. He felt that his foster parents had done something very unjust because they did not disclose the most important thing there could be to a boy, namely his parentage. That was why he deserted, and he never wanted to live with them again.

Comment.—This boy's problems are not so simple. His early life was quite unsettled and in addition there is the definite problem of overt homosexuality. We do not have sufficient material to offer an etiological solution of his sexual inversion, but certain things pertain to our problem. This boy presents: (a) a preliminary period of uncertainty regarding parentage; (b) resentment at not having been sooner informed; (c) persistent home desertions after this disclosure. In addition to the above, this boy had certain other ideas, which are, however, related to his highly withdrawn, egocentric and hostile attitude. He tended to adopt a paranoid attitude. He spoke of the people about him being his enemies, nobody wants him or loves him. He spoke of suicide in a melodramatic way. This is a boy who is perhaps generally destined to react in a paranoid manner, faced with the more specific problem which concerns us here. His specific reactions lie within the general framework of this attitude and are somewhat molded by it.

CASE 3.—J. L. a white boy of 15.

Family Background.—Nothing is known of the boy's real parents. He was adopted from a foundling home at the age of three. Both parents are immigrant Italians who came to the United States before they were 20. The father is an unintelligent, friendly, cheerful man who owns his own ice business. Very sincere, cooperative and interested in the boy. The mother has been recently working in a factory to save money for the boy's future care. Somewhat moralistic. Both parents have always been very ambitious and very indulgent with regard to the boy and never disciplined him severely. The home is good, the rooms are large, well kept and well furnished. The neighborhood is good, not crowded, and populated by middle class Italians.

Boy's Development.—Nothing is known of the pregnancy or delivery. He suffered the usual childhood illnesses. He always mingled well with other boys and engaged in sports. His conduct in school has been variable. In the last few years, it has not been very good. He repeated both grades 7A and 7B.

Boy's Problems.—The first court appearance was about one year before commitment when the parents brought him into court because he was uncontrollable and deserting home. His behavior had been especially bad during the last year, but for the two years previous, the behavior problem had been slowly developing.

For years, he had heard rumors that he was an adopted child but no one had ever definitely proven it to him. He does not look like an Italian. Although his attitude to his parents had always been one of respect, he began to gamble, be incorrigible, steal from home and persistently run away. One year ago, his father overheard the boy tell someone that his parents were not really his own. This provoked a violent outburst and the father produced a birth certificate which the boy, however, believes is a forgery. Following this occasion of the problem coming out into the open, the boy's behavior became markedly worse. He violated probation and was committed to the New York State Training School for Boys.

Institutional Findings.—Examination disclosed no physical defects. The I. Q. was 98, the E. Q. was 96 with an eighth grade educational achievement. He was especially poor in arithmetic and language usage. He was erratic, irresponsible, moderately aggressive. Interviews disclosed a quiet cooperative boy who had no conscious feeling of guilt over his stealing or misbehavior. He described the pleasures of tormenting shopkeepers and the enjoyment and excitement when stealing. He became emotionally disturbed when discussing his parentage. He stated, "Maybe they are, maybe they aren't." The reason he gave for running away was fear of punishment after stealing from home. He described vivid fantasy of adventure and glory. On his frequent runaway escapades, he never had any definite place to go nor were there definite incidents which provoked the individual runaways.

Comment.—This boy was for years faced with the question of his parentage. There are no other discernible causes for a behavior disorder either in the environment or in the family situation. The behavior disorder was rather diffuse in its manifesta-

tions. When the problem was brought into the open, his foster father failed to convince him. The boy's appearance was decidedly different from that of his parents. He discussed all his affairs casually except the matter of his parentage. The boy demonstrates: (a) a still present doubt as to his parentage; (b) a diffuse type of behavior disorder in which deserting home is a prominent symptom; (c) runaway episodes which are unprovoked by external situations; (d) an aggravation of the disturbance when the problem came to the surface. It is interesting that when interviewed, this boy expressed no resentment or hostility to his parents even though the problem of parentage was admittedly perplexing him. His conscious attitude to them was one of love and affection.

CASE 4.—L. McQ. a colored boy of 16.

Family Background.—The father's name is known, but he disappeared and has not been seen since the birth of the child. The mother was unmarried and gave birth to the child when she was a young girl. She boarded the child out in early infancy, and saw him only occasionally until he was two years of age. She left the South then, and the foster mother knows vaguely of some northern city where the mother might be, but the mother never saw her son after that. At the time the foster mother took the boy she was a widow of 10 years' standing, and had a 15-year-old son. She was a hotel domestic, and took the child with her when she went out to work. When the boy was nine she moved to New York and continued doing the same kind of work. When the boy was 11 she joined the followers of Father Divine. The present home of the foster mother is shabby, dirty, but self-supporting and not on relief.

Boy's Development.—Nothing is known of the pregnancy or the delivery. The baby was unusually fat and started walking late. There was a severe pulmonary illness at the age of one and the usual childhood illnesses. Schooling in the South was haphazard.

The Boy's Problem.—After the mother joined the Father Divine group she felt that she had to tell the truth in everything, so she decided to tell the boy that she was not really his mother. She did this when the boy was 11, and has ever since felt that it was a terrible error, because she has never been able to control him since. She stated that after that he was disobedient, became a truant, stayed away from home, and was generally incorrigible. She tried to impress the teachings of Father Divine on him, but without effect. There were, however, some external factors operative at the same time. When the mother joined the Father Divine cult, she assumed a job with irregular hours, making her supervision of the boy quite poor. When the boy was 13, they lived apart for a period of five months because the cult regulations demanded that males and females should live separately. Reports from the city schools stated that he was sullen, disrespectful, seemed to be carrying a grudge, and was a truant. He was an energetic boy who always managed to

earn money by working whenever he wanted to. The foster mother finally had him committed to the New York State Training School for Boys.

Institutional Findings.—Examination disclosed no physical defects. The I. Q. was 74; the E. Q. was 74, with an educational achievement of sixth grade work. He was resentful to routine, avoided work, and was somewhat aggressive. Interviews disclosed a friendly boy who had difficulties in intellectual comprehension. His answers to questions were vague, indefinite and uncertain. His memory was poor. He had no insight into the anti-social nature of some of his acts. He disliked school and gave a poor history of himself. He stated that his real mother had been sending him letters for a long time. This is probably fantasy. He did not verbalize any emotional reaction to having learned about his parentage. He stated without emotion that he would rather live with his mother than his foster mother. He ran away from home to avoid punishment. He did not bear out the strongly felt conviction that, to the foster mother's mind, the disclosure of his parentage was her great mistake, and marked the onset of her loss of control over the boy.

Comment.—This boy is dull, with definite disability in comprehension and verbalization. Certain external circumstances aided the development of his difficulties. He demonstrates the development of a diffuse behavior disorder definitely following the disclosure of his parentage. In interview, the boy did not confirm the foster mother's firm belief in the cause of her abrupt loss of authority over him. However, he was of about borderline intelligence, and gave a poor story of all his affairs. This boy demonstrates: (a) an abrupt development of a diffuse type of behavior disorder in which home desertion was a prominent feature following the disclosure; (b) the fantasy of communication with the real, but absent, parent; (c) complete lack of insight and understanding in a borderline mental defective.

Case 5.—R. A. a colored boy of 14.

Family Background.—The boy was the product of an illegitimate union between a widow who had 12 children by her marriage and a man who deserted when the baby was born. The mother died following an accident when the boy was two years of age. He was then taken by a distant cousin who was married and childless, and was brought up as her own son in a semi-rural community in New Jersey. When he was 10, the cousin gave birth to a child of her own. Shortly thereafter, she felt that the boy was a nuisance and a bother, and at the age of 12, insisted that he be cared for by two of his half-sisters who were living in New York City. The two unmarried sisters took him into their home. It was a small apartment in a congested Harlem district. One of the sisters had an illegitimate baby. The older sister who assumed guardianship was sadistic and hostile, and very unsympathetic with any of the boy's problems.

Boy's Development.—The pregnancy and delivery were normal. He was bottle fed, had the usual childhood diseases, and fractured one arm in several falls. He suffered from night terrors until the age of four, and was a thumb sucker until eight. He was an attractive, popular boy, and was quiet and obedient in the home. In school he was tractable, with no problem of truancy until he was transferred from standard 4A grade to an ungraded class.

The Boy's Problem.—Until the age of eight, he looked upon his foster parents as his real parents. They were very attentive and treated him as their "own child." At that time, some boys in the neighborhood told him that he was only an adopted boy. He went to his foster-mother and asked her. She explained the truth to him. This was quite a shock to him, and he thought about his real parents every day, and often wondered what they looked like. However, there was no change in the boy's external behavior, and his foster parents continued to treat him kindly. At the age of 10 the baby was born to his foster parents. It was after this that the latter began to try to rid themselves of our subject. At the age of 12 he went to live with his sisters and his adjustment was uniformly poor. He was mistreated and because of his general feeling of dejection and unhappiness, tried on three occasions to commit suicide. He would stay out late at night, did not obey his sister, and was generally incorrigible. However, there is no record of anti-social behavior in the form of stealing. He frequently ran away from home, and when brought back, would refuse to enter the house. The sister was anxious to rid herself of the boy and had him committed to the New York State Training School for Boys.

Institutional Findings.—Examination disclosed no physical defects. The I. Q. was 67. The E. Q. was 64, with an educational achievement at the third grade level. There was a severe spelling deficiency. His adjustment in our school and cottages was poor; a constant troublemaker. Interviews disclosed a glib, talkative youngster who spoke in a jerky manner. He cried as he discussed the problem of his parentage. He stated that he was very happy living with his foster parents, and that it took him a long time to believe that they were really not his own. He could not recall the occasion of the birth of his foster brother. He stated that his foster parents did not want to send him away, but that he wanted to go to New York. However, in New York, he was hopeless and dissatisfied with his sister.

Comment.—This boy is a high grade moron, and the truancy from school can be attributed to that fact. This boy did not develop any behavior disorder on learning of his real parentage, but only after his foster parents rid themselves of him. No doubt their own attitude to him suffered a marked change on the birth of their own child. He demonstrates: (a) the extreme difficulty and delay in accepting the validity of the all important truth about the parentage, (b) fantasies of what the real parents looked like, (c) repression of the incident of the birth of the real son to the foster parents,

(d) the difficulty of adjusting to other parent substitutes under other conditions.

CASE 6.—W. D. a colored boy of 15.

Family Background.—The boy was born out of wedlock. When nine months old, the father took him away from the mother. He subsequently married another woman and had another son and two daughters. Our subject was raised as the oldest son of the family. The home was clean, but in a congested Negro district.

Boy's Development.—Nothing is known of the pregnancy or delivery. He suffered the usual childhood diseases. He attended school to grade 8A, though he was a definite problem of truancy. His conduct at home was satisfactory, he was always given spending money within reason. His father wanted him to be a lawyer. He did not participate in organized recreational activity.

The Boy's Problem.—When the boy was 10, his real mother suddenly appeared in the school yard and tried to grab him. She was unable to secure the boy, and tried to regain the custody of him by court action, but failed. The boy stated that his school difficulty began at about this time. When he was 13, his father told him that his real mother had tried to poison him as an infant. He told him this, "in case I die I want you to know what kind of a woman your mother is." At the age of 14, he stole 60 cents in an elevated station. Later he robbed an elevated station again. Although his behavior at home continued to be good, his father had him committed to the New York State Training School for Boys.

Institutional Findings.—Examination disclosed no physical defects. Interviews showed the boy to be tense; he looked aside when speaking. He often paused suddenly in the midst of talking and seemed to be in a trance. He described auditory and visual hallucinations, he saw visions, heard music and poems. His conscience often spoke to him and told him what to do. He would talk things over with his conscience, sometimes he obeyed it and sometimes not. He was highly superstitious and had faith in certain numbers. He had a hypertrophied interest in money and the power of money. He wanted to have money to be a powerful person so that his foster mother would think he was the most powerful person in the world. He always felt badly because his real mother didn't want him. He was very evasive in discussing his parentage. At first he said his foster mother was his real mother. Usual routine questions were answered coherently and logically, but to some questions, his answers were irrelevant and seemed to have no logical relationship. In response to direct questions about parentage: Q. "Did you behave differently after you learned that your mother was not really your own mother?" A. "Some of my friends do not understand why I act the way I do."

Comment.—This last question and answer demonstrate nicely a superficial irrelevance which can be readily dissipated by a knowledge of the boy's problems. This boy had obsessive and schizophrenic symptoms. The point of interest here is the perti-

nence which the problem of the boy's parentage had to the destruction of his conversational forms, as evidenced by the break in the conscious, logical relationship between answer and question. In other words, this problem, among his many others, was a sufficient source of anxiety to operate as an emotional block in destroying the logicality of some segments of his conscious thinking.

CASE 7.—F. W. a colored boy of 14.

Background and Problem.—An illegitimate child deserted by both parents when he was two weeks old. He was brought up by foster parents until the age of 11. We do not know whether he was brought up as a foster-child or led to believe he was a real son only to learn the truth later. However, he became a severe problem of home desertion and truancy and was committed to the Brace Memorial Farm. He continually escaped, was an unwholesome influence on other boys, had an undue interest in sex, and was subject to violent fits of temper and vicious burst of aggression. At the end of three years, his foster parents refused to take him back and he was committed to the New York State Training School for Boys.

Institutional Findings.—Physical examination disclosed chronic tonsillitis, but otherwise no defects. The I. Q. was 88, the E. Q. was 76 with a fourth grade educational achievement. He was a constant discipline problem and had a vicious temper. At first, interviews disclosed him to be cheerful and friendly, but as time went on, he became uncooperative and hostile. He had definite paranoid ideas and ideas of reference. He felt that people looked at him in a peculiar way, that he was being tested out, that he was being framed. He experienced vivid fantasies, usually of having sexual intercourse. He had fantasies of a girl coming to him and saying that she was his sister and that she led him to his mother who begged his forgiveness for having deserted him. He forgave her and everyone was happy. The boy was in tears as he described this fantasy. He carefully refrained from condemning his mother for deserting him. "I don't know the conditions so I can't judge."

Comment.—While this case does not fit exactly into the pattern of those previously mentioned, it is included because of the interesting fantasy production, that of finding his mother and her begging for forgiveness.

GENERAL COMMENT.

Several points of accessory interest should be noted. All but one of the boys were colored. They were all brought up either as the only child or else as a much younger child than any of the other foster-siblings, with one exception. This would certainly tend to make the shock of the disclosure especially great.

From the standpoint of general symptomatology, some of these cases demonstrate a period of preliminary doubt concerning the parentage, or a persistence of the doubt even after the problem has been consciously faced. There may be marked difficulty of adjustment to other parent substitutes and subsequent foster homes.

Conscious fantasy formation is a prominent symptom. This may be in the nature of the mother coming to claim the son, or of communication with the parent, or of speculative fantasies concerning the possible appearance of the parents. There may be fantasies of finding the mother, and atonement and forgiveness. Or there may be fantasies of the parents not wanting the child. None of these boys demonstrated any conscious fantasy of revenge for having been deserted.

The outstanding subjective attitude adopted after the disclosure is resentment to the foster parents, and the most characteristic feature of the behavior pattern is desertion of the home. There may be an aggravation of a pre-existing behavior disorder, or behavior disorder may be newly precipitated. The home desertion may be motivated by conscious resentment, or may be purposeless and apparently irrational. It is interesting to note that the boy J. L. did not have any resentment to his foster parents, and F. W. did not have any hostility to his real mother. Both boys were careful to state that position. It would be easy to assume that a strong hostility was repressed and then redirected in an anti-social manner. Note should be made, in all the runaways, of the absence of any conscious motive to seek out and find the real parents. One could reasonably assume that such a motive might exist in these boys, even though repressed from consciousness.

In problems of a more severe nature, paranoid and schizophrenic reactions, one can note an occasional one of the above symptoms within the framework of the more malignant picture. In mental defectives, one may be faced by a behavior disturbance, with little or no subjective reflection of the problem.

It is no doubt true that many normal children developing in normal families often have transient fantasies of doubt concerning their parentage. This is probably due to transient hostilities or feelings of rejection which may be generated even in the course of the most smoothly functioning family unit. Under ordinary

circumstances, though, the fundamental security and love relationships in a normal home will always suffice to dissipate these fantasies. It is quite possible that neighbors and relatives can accidentally drop hints to an adopted child which might set a train of doubting fantasy going; or that the foster parents, in spite of strong love for a foster child may still be unable to prevent an alert child from feeling a certain lack of fundamental security in the relationship. Be that as it may, a good percentage of the cases here cited demonstrated this doubt.

The confirmation of the doubt is of course the major trauma. The emotional security within the family unit is badly shaken, and the attitudes to authority and society suffer. Perhaps the most pernicious result is the development of an ambivalent attitude to the foster parents, love for the past care and affection, and hate for the withdrawal of the security of that relationship. This resentment and hostility may be expressed by acts against the foster parents or against society.

The resentment to the foster parents or parent may be completely repressed and find its overt expression in anti-social behavior.

Summary.

1. The problem of the disclosure of foster parentage is discussed and seven cases are presented.

2. The general symptomatology is presented, and its occasional interrelationship with definite mental disease briefly touched upon.

Proceedings of Societies.

THE AMERICAN PSYCHIATRIC ASSOCIATION

PROCEEDINGS NINETY-THIRD ANNUAL MEETING.

HOTEL WILLIAM PENN, PITTSBURGH, PA.,
MAY 10-14, 1937.

TUESDAY MORNING SESSION.
MAY 11, 1937.

The ninety-third annual meeting of The American Psychiatric Association convened in the Hotel William Penn, Pittsburgh, Pa., at ten-ten o'clock, the President, Dr. C. Macfie Campbell, of Boston, Mass., presiding.

PRESIDENT CAMPBELL.—I have the honor of calling to order the ninety-third annual meeting of The American Psychiatric Association.

I shall ask the Reverend Bernard C. Clausen, of the First Baptist Church, to deliver the invocation.

REVEREND BERNARD C. CLAUSEN.—By the faith that the wild flower shows as it blooms unbidden, by the calm of the river that flows to a goal that is hidden, by the strength of a tree as it clings to its deep foundation, by the courage of birds' light wings on their long migration, beautiful spirit of trust that abides in nature's breath, teach us how to confine and live our lives and to rest. Amen.

PRESIDENT CAMPBELL.—Our colleagues of Allegheny County and of Pittsburgh have been good enough to send representatives to greet the Association. I have pleasure in asking the President of the Allegheny County Medical Society to address the Association, Dr. Sidney A. Chalfant.

DR. SIDNEY A. CHALFANT.—*Mr. President, Members of The American Psychiatric Association and Friends:* There are certain compensations for being elected to office sometimes, and one of them today is the pleasure it gives me as President of the Allegheny County Medical Society to welcome you to Pittsburgh. We assure you that we are anxious to make your stay as pleasant as possible. Your program would indicate that your meetings will be both profitable and stimulating.

Pittsburgh has for years been the center of the steel and coal industries. Many of the men who have made their fortunes in this city have gone East, to New York, Philadelphia, and other cities, and have there given their

funds to institutions in the East. Some of the men who have gone East may not have been much credit to us, but there was opened last week an outstanding institution in this city, given by Pittsburgh men. I refer especially to Mellon Institute of Industrial Research. I am quite sure that a trip to the Mellon Institute will be well worth while. They are solving many problems of science and industry, to the help of the industrial world.

We are also proud of our hospitals, and they possibly, although they are general hospitals, might be of some interest to you. Being associated with the new Allegheny General, I would especially speak for that institution which is the most recent one in the city.

We shall have soon, and I think it will be started promptly, a new psychiatric hospital, a state hospital in the city, which will be for the treatment and diagnosis of incipient cases.

If we have a clear day and a clear night, and we do have them sometimes in Pittsburgh, it would be quite worth your while to make a short trip up to Mount Washington. It will give you a view of the city that is unique.

We hope that when you leave Pittsburgh, you will take with you a recollection of a pleasant time and the desire to come back to see us.

PRESIDENT CAMPBELL.—The President of the Academy of Medicine of Pittsburgh has come also to greet the Association.

I have great pleasure in presenting Dr. James K. Everhart.

DR. JAMES K. EVERHART.—*Dr. Campbell, Members of The American Psychiatric Association and Guests:* At the time I was requested to say a few words at this meeting, it was intimated to me, very delicately of course, that I might, if I liked, make my remarks very brief, that the really important part of this program after all is the address of your President. I know that you will all feel relieved that I intend to follow that suggestion.

Any organization which has attained its 93d birthday has a claim to distinction. When to this is added your history, your record of achievement and your service to psychiatry with all that you have accomplished, it seems to me that to distinction can be added fame.

We honor The American Psychiatric Association for what it is and for the prospects of future and even greater accomplishments. You are here not by accident at all nor to be entertained nor yet merely to entertain, but because of a deep purpose to further the service of psychiatry which is another way of saying service to general medicine and thereby service to mankind.

It gives me no small degree of pleasure to extend to you all a very cordial and whole-hearted welcome from the Pittsburgh Academy of Medicine. For many years a number of our members have been affiliated with The American Psychiatric Association and have taken active part in your deliberations. So to all of you, whether members or guests, we want to bid a hearty welcome. We hope that reflections upon this year's meeting will always bring to you pleasant and delightful memories.

PRESIDENT CAMPBELL.—I shall ask Dr. Chapman, President-Elect, to respond to these cordial words of welcome from our two colleagues. Dr. Chapman!

DR. ROSS MCC. CHAPMAN.—May I thank you, gentlemen, on behalf of The American Psychiatric Association, for your warm words of welcome. We appreciate deeply the greetings of the Allegheny County Medical Society and of the Academy of Medicine and feel sure that we shall take away from your city impressions that are lasting, memories that are most happy. We who come from a distance know Pittsburgh as a great industrial center, but we also know of it as a city of wide educational interests and a city of broad culture. Again, I thank you!

PRESIDENT CAMPBELL.—We would like now to have reports from the chairmen of two committees, the first from the Chairman of the Committee on Arrangements, Dr. Frederick.

Dr. John N. Frederick, Chairman of the Committee on Arrangements made several announcements regarding the program.

PRESIDENT CAMPBELL.—I should like to ask the Chairman of the Committee on Program, Dr. Hall, to make any communication which he thinks fit to make.

DR. ROSCOE W. HALL.—*Mr. President, Members of the Association and Guests:* There is one change and one addition to be noted. If you will turn to page 32 of the program, the meeting this afternoon in Section III, Studies from the Laboratory, the paper by Dr. Marshall on "Psychoallergic Desensitization by Non-Specific Means," through an unfortunate misunderstanding will not be presented. It will, therefore, be scratched. In its place will be the paper by Dr. Emerick Friedman, which is described on page 79 under the additional papers to be read by title. This paper, "The Irritative Therapy of Schizophrenia," will be discussed by Dr. Solomon Katzenelbogen and Dr. Meyer Amdur.

The addition. By request, there will be a round table on hypoglycemia, the moderator of which will be Dr. Bernard Glueck, and among the discussants will be Dr. Manfred Sakel and Dr. John Ross. This round table will be held at the same hour as the other round tables on Thursday evening at seven o'clock.

PRESIDENT CAMPBELL.—The next piece of business is the report by the Secretary-Treasurer of the Council and his report as Secretary-Treasurer. Dr. Sandy!

SECRETARY SANDY.—The report of the Council.

The Council met at the William Penn Hotel, Pittsburgh, May 10, 1937, at 7.30 p. m. Fifteen members were present, President Campbell presiding.

Dr. Appleton H. Pierce, at his request, was afforded an opportunity to make a statement as to the present policy of requiring an applicant for reinstatement after being dropped for non-payment of dues to pay dues for

the whole period of time during which he had not been a member. After much discussion, further action was postponed for consideration at a later meeting of the Council.

The Secretary reported changes in membership as follows: Three Members and three Fellows have resigned, two of the Members and one Fellow owing dues for 1937. The Council voted to accept the resignations remitting the 1937 dues in the cases of the two Members and one Fellow.

It was recommended that service be discontinued including the JOURNAL in the case of 10 Fellows, seven Members and three Associate Members two years in arrears, a letter to be sent each member notifying him of the action taken.

In view of the illness of Dr. Arthur S. Hamilton, his long membership and other circumstances, the Council voted to remit his dues, discontinue the JOURNAL, but to retain his name in the list of members.

The Council voted to drop from the Association nine Fellows and nine Members three years in arrears in dues, two notices and a special letter having been sent to them.

The Council approved for Life Membership the following who were elected to Active Membership in 1907:

Dr. Charles W. Burr, Philadelphia, Pa.

Dr. L. Vernon Briggs, Boston, Mass.

Dr. Earl H. Campbell, Newberry, Mich.

Dr. William W. Richardson, Mercer, Pa.

Dr. Cheney presented the report of the Board of Examiners, based upon which the Council voted to recommend for election 31 applicants for Associate membership, 159 applicants for membership, one Member for reinstatement, 12 to be transferred from Associate Member to Member, and 11 to be transferred from Member to Fellow. No one was recommended for honorary membership.

Dr. Dayton, Chairman of the Committee on Nomenclature and Statistics, submitted supplementary paragraphs to be added to the report of his committee in regard to the problem of a more satisfactory mental base for the determination of intelligence quotients in adults. The amended report of the Committee on Nomenclature and Statistics together with the reports of the following committees, namely, the Executive, Research, Psychiatric Nursing, Standards and Policies, and Legal Aspects of Psychiatry, were accepted and approved for printing with the proceedings.

Consideration of the reports of the Committees on Public Education, Psychiatric Social Service and Psychiatry and Medical Education was postponed for further discussion.

No report was filed by the Committee on Ethics.

The Council voted that the incoming President shall designate a successor to Dr. Farr on the National Research Council and also a representative to the American Association for the Advancement of Science.

Upon motion of Dr. Overholser, seconded by Dr. Treadway, the Council authorized the incoming President to appoint such Fellows, not to exceed five

in number, as may plan to attend the Second International Congress for Mental Hygiene to represent the Association.

The application of the Connecticut Society of Psychiatry for affiliation with the Association was accepted by the Council, upon motion of Dr. Cheney. seconded by Dr. Brill.

After considerable discussion, upon motion of Dr. Cheney, seconded by Dr. Stevenson, the question of a certificate of membership for the various classes of members was postponed until a further demand was received for a consideration of the same. In the meantime, at the suggestion of Dr. Jackson, it was recommended that the Association issue a card such as is used by the American Medical Association indicating membership in good standing.

The Secretary reported that upon investigation it was found inadvisable and impractical at this time to establish a trust fund of the resources of the Association.

After a general discussion of the suggestion of the Executive Committee, the Council voted not to raise the dues of the member class.

The Secretary read a letter of appreciation from Dr. Wagner-Jauregg for the congratulations of the members on his eightieth birthday.

The Secretary also read a letter from Dr. Ley, of Belgium, expressing his deepest condolence for the loss of the distinguished member, Dr. White.

The Council voted to acknowledge a communication of the Mutual Liability Insurance Company and that it be tabled.

Dr. Overholser read the following resolution, which was passed by the Council for recommendation to the Association:

"WHEREAS, Several organizations interested in promoting human welfare have manifested a deep interest in research into the causation, prevention and treatment of mental diseases and have furnished substantial financial aid to the prosecution of such research; and,

"WHEREAS, Certain legislative bodies and others interested, including the Josiah Macy, Jr., Foundation, the Rockefeller Foundation, the Markle Foundation, and the Supreme Council of the Scottish Rite of Free Masonry for the Northern Masonic Jurisdiction, have been outstanding in giving moral and financial support to such research; be it

"*Resolved*, That The American Psychiatric Association on behalf of American psychiatry hereby record its gratitude for the valuable service rendered to it because of psychiatric research by these organizations and that it heartily endorse the importance of studies looking to a solution of the problems of mental disease."

The Council then informally discussed the invitations from various places for the 1938 meeting, it being decided that only those would be considered which came from members or groups of members. Dr. Glenn Myers spoke at length in regard to the invitations received from the Los Angeles and San Francisco group. Further consideration was postponed for a later meeting of the Council, at which time representatives from other places will be heard.

The meeting adjourned at 11.10 p. m.

PRESIDENT CAMPBELL.—The report of the Council is before you. What is your wish with regard to this report?

It was regularly moved, seconded and carried, that the report of the Council be adopted.

PRESIDENT CAMPBELL.—I shall call on the Secretary for his report as Secretary.

SECRETARY SANDY.—The following is a statement of the membership of The American Psychiatric Association as of April 15, 1937—I shall condense this quite a bit, the report as a whole being printed in the proceedings. The present number of Honorary Members is 19; Life Members 59; Corresponding Members 4; Fellows 887; Members 684; Associate Members 79.

The total membership April 15, 1936, was 1661. The total membership April 15, 1937, was 1732, or, a gain of 71.

PRESIDENT CAMPBELL.—What is your wish in regard to this report of the Secretary?

It was regularly moved, seconded and carried, that the Secretary's report be adopted.

PRESIDENT CAMPBELL.—Dr. Sandy will present the report of the Treasurer.

SECRETARY SANDY.—The following statement of the Treasurer is based upon the report of a certified public accountant. I shall also condense this, the full report being printed in the proceedings.

Total balance April 16, 1936, was $28,569.21; total receipts this year were $14,794.23, making a total of $43,363.44. The total disbursements were $14,083.67, leaving a total balance of $29,279.77.

In the account of the AMERICAN JOURNAL OF PSYCHIATRY there was a bank balance April 16, 1937, of $1,832.47; the total receipts for the year were $8,970.61, making a total of $10,803.08. The total disbursements of the AMERICAN JOURNAL OF PSYCHIATRY were $9,438.67, leaving a balance of $1,364.41, or the total cash resources of the Association were $30,644.18.

PRESIDENT CAMPBELL.—The report of the Treasurer has been gone over by public accountants, still it has to be submitted to the Auditors of the Association, after which it will come up for disposal by the Association.

It is usual for someone to move that a Committee on Resolutions be appointed. I shall be glad to entertain such a motion from the floor.

DR. BRILL.—I so move.

The motion was seconded and carried.

PRESIDENT CAMPBELL.—I should like to appoint Dr. George H. Stevenson, London, Ontario, Dr. Frank E. Leslie, Northampton, Mass., and Dr. Titus H. Harris, Galveston, Texas, as the Committee on Resolutions.

Since our last meeting, death has taken its toll of members of our Association. I shall ask the members to rise while the Secretary reads the names of the departed members.

The audience stood in tribute to the deceased members as Secretary Sandy read the names, as follows:

Abdu M. Ibrahim, M. D., Northampton, Mass., died Jan. 15, 1936.
Hugh A. McKay, M. D., Toronto, Ont., Canada, died Feb. 14, 1936.
Charles A. Baragar, M. D., Edmonton, Alb., Canada, died Mar. 8, 1936.
George E. Clark, M. D., Providence, R. I., died Mar. 14, 1936.
A. Marois, M. D., Quebec, Canada, died Apr. 9, 1936.
George W. Stephens, M. D., Natchitoches Parish, La., died Apr. 26, 1936.
Henry O. Spalding, M. D., Hingham, Mass., died May 10, 1936.
James Monroe Austen, M. D., Columbia, S. C., died May 24, 1936.
Alberta S. B. Guibord, M. D., Waban, Mass., died May 27, 1936.
Clarence A. Patton, M. D., Philadelphia, Pa., died June 2, 1936.
James L. Tower, M. D., Wassaic, N. Y., died July 10, 1936.
Charles G. Chaddock, M. D., St. Louis, Mo., died July 20, 1936.
Eugene A. Stanley, M. D., Waterbury, Vt., died Aug. 19, 1936.
William H. Mayer, M.D., Pittsburgh, Pa., died Aug. 23, 1936.
John Percy Wade, M. D., Catonsville, Md., died Aug. 27, 1936.
Frankwood E. Williams, M. D., New York, N. Y., died Sept. 24, 1936.
George E. Poor, M. D., Framingham, Mass., died Oct. 29, 1936.
William D. Stewart, M. D., Weston, W. Va., died Nov. 2, 1936.
Henry J. Gahagan, M. D., Aurora, Ill., died Nov. 10, 1936.
William H. Pritchard, M. D., Columbus, Ohio, died Nov. 11, 1936.
Berthold A. Williams, M. D., Cincinnati, Ohio, died Nov. 18, 1936.
Jau Don Ball, M. D., San Francisco, Calif., died Nov. 25, 1936.
Dorian Feigenbaum, M. D., New York, N. Y., died Jan. 2, 1937.
William G. Stearns, M. D., Winnetka, Ill., died Jan. 11, 1937.
Ferd De Forest Streeter, M. D., Rochester, N. Y., died Jan. 20, 1973.
Barbara Curtis, M. D., Buffalo, N. Y., died Jan. 25, 1937.
Edwin E. Evans, M. D., Columbia, Mo., died Feb. 8, 1937.
William A. White, M. D., Washington, D. C., died Mar. 7, 1937.
Harris A. Bolton, M. D., Warm Springs, Mont., died Mar. 17, 1937.
E. A. Farrington, M. D., Haddonfield, N. J., died Apr. 5, 1937.
H. Irving Cozad, M. D., Cuyahoga Falls, Ohio, died Feb. 1, 1937.
Archibald J. Kilgour, M. D., Kingston, Ont., Canada.
Edward H. Kinsman, M. D., Toronto, Canada.

The dates in the last two cases, we do not have.

PRESIDENT CAMPBELL.—Among those whom we have lost recently was one who referred unusual luster on the Association, a distinguished Past President. I shall ask President-Elect Chapman to present the memorial to William A. White.

Dr. Chapman read the memorial to Past President William A. White.

William Alanson White, M. D.

1870–1937.

It is hard to realize that our friend William Alanson White is no longer with us; that his pen has ceased from its toiling; that his great voice is stilled. But what happy memories he has left to us of a glowing personality, of inspiring speech, of stimulating example and of a man who, giving of himself to the utmost in his chosen field of medicine, did more than anyone else to make this association what it is today. His written word will speak for him down through the years to come, but one wishes it were possible to portray clearly in some indelible fashion the greatness of the man, the enduring values of this living personality.

Dr. White was born in Brooklyn, N. Y., on January 24, 1870, the son of Alanson and Harriet Augusta (Hawley) White. He received his preliminary education in the public schools of that city and being as he says "poor," grasped the opportunity to try examinations for a four year scholarship at Cornell. He passed those examinations and at the age of 15 left his home for Ithaca where at 19 he graduated. The men whom he tells us influenced him most during these important formative years were Prof. Burt G. Wilder, with his work on brain morphology; Prof. Simon Henry Gage, in histology and embryology; Prof. Henry S. Williams, in geology and paleontology; Prof. John Henry Comstock, in entomology; and finally Prof. Jacob Gould Schurman of the Department of Philosophy. The influence of these great teachers was profound and had much to do with bringing about his determination to study medicine. He then at 19 entered the Long Island College Hospital Medical College where at 21, in the year 1891, he was given his medical degree. There followed experience as an emergency hospital ambulance surgeon and house surgeon, and on the alms and workhouse medical staff of Blackwell's Island. Finally he returned to the staff of the Long Island College Hospital from which he had graduated and it is significant that there he associated himself under Dr. William Browning with a dispensary receiving nervous diseases. In 1892 there came to him the opportunity to join the medical staff of the Binghamton (N. Y.) State Hospital as an assistant physician. It was here under that able medical superintendent, Dr. Charles G. Wagner, that Dr. White received his training in hospital administration. His 11 years at Binghamton were years of growth. It was during this period that great strides were being made in the introduction of better medical and surgical attention. The training school for nurses in the mental hospital came into being. One would like to pause here to tell some of the stories still told in Binghamton and elsewhere of the White of those times, incidents of the hospital day, of his social proclivities, his love of the theater, his musical interests and the entertainments for patients which he helped put on. For his chief interest then, as afterward, was always in his patients and he sought constantly to know and understand them better. This drive to better understand the language and behavior of patients was vastly stimulated by his visits to the newly established Pathological Institute in New York City where

he met and became friendly with Boris Sidis, then working with hypnosis on problems in "Mental Dissociation."

Speaking in his "Forty Years of Psychiatry" of his experience with Sidis, which seemed to him "crucial," White says, "Almost without knowing it I absorbed the rudiments to what was subsequently to be the doctrine of the unconscious and accepted from the very beginning in my attitude toward these problems the principle of determination in the psychological field."

Another event of first importance which occurred in the summer of 1896 was his meeting with Smith Ely Jelliffe of New York who was spending some months at the hospital in study. From this early association there developed a close friendship, of great benefit to both and to American psychiatry, which endured to the end.

Dr. White had for some time held the position of first assistant physician at the Binghamton State Hospital when the opportunity came for him to seek the office of Medical Superintendent at St. Elizabeth's Hospital in Washington, D. C. He applied for the position and in 1903 was appointed by executive order of Theodore Roosevelt, then President.

There followed several most difficult years of reorganization and completion of extensive building construction which had been interrupted by the death of his predecessor. The St. Elizabeth's which he found was in many respects far behind the times, not only as to construction of old buildings and inadequate hospital facilities but as to the actual care and treatment of patients. He was beset by labor difficulties and by the petty schemes of politicians; there were hangers-on and plotters against him. He was forced to submit to investigation after investigation. He won through, but no man without his infinite patience and rare judgment could have accomplished in those first years what he did in laying the foundations of the St. Elizabeth's of today, a modern psychiatric hospital adapted in construction and organization to meet ever-changing conditions and demands. And as he built his hospital and defined its policies so he himself grew in the esteem and affection of the community and in the respect of Washington officialdom. As to the latter the many occasions on which his advice on government projects and policies was sought bear witness.

He was a great hospital administrator. The welfare of his patients remained always his first consideration and he saw to it that that was the attitude of his staff. He saw each Monday every patient who had been admitted during the week preceding. For many years, until the growth of the hospital and his increasing responsibilities made it impracticable, he conducted the daily clinical staff conferences. He could delegate authority. He selected his man, defined his responsibilities and told him to go ahead and do his job. There was rarely interference.

In the face of mistakes or of hospital catastrophe of one sort or another his reaction was invariably, "How can we capitalize on this? How can the hospital benefit in the future?"

He had a remarkable optimism and an unusual tolerance. He loved his fellow man and he believed in him. If one of his staff proved weak he sought

for such elements of strength as existed and built on that, and again and again his course was justified.

He urged the young physician to write—to put his thoughts on paper—and many a paper found its way into print, less it seemed sometimes on account of the value of its contents than that he felt its publication would be an incentive.

His contact with the various hospital departments remained through the years surprisingly close for one involved in so many time consuming interests. Dr. White gave the impression at times that hospital responsibilities slipped easily from his shoulders. Nothing could have been farther from the truth. His hospital responsibilities were constantly with him, at home or abroad, and when on vacation or ill he was in daily communication and in command of the situation, most frequently through his good friend and faithful secretary for 26 years, Arnold Barbour. St. Elizabeth's was a great part of his life. His genuine enthusiasm over a new dining room or operating room or special clinic equalled apparently his feeling for a new method of treatment or some new scientific venture and was a joy to see.

He was a champion of the large hospital from the point of view both of economy and, when well organized, as affording the best opportunities for clinical and research activity.

St. Elizabeth's grew in his administration from 2300 to nearly 6000 beds.

He was the first to develop within a mental hospital a special department of internal medicine for the benefit of the physically ill and for research purposes. He took justifiable pride in his new laboratory building and in his finely arranged and equipped Medical and Surgical Building completed only three years ago. He was progressive—always in the forefront of medical advance. He was the first in this country to undertake the malarial treatment of general paresis.

Grateful acknowledgment must be made of his fight of more than 30 years to do away with the archaic jury trial for purposes of commitment in the District of Columbia through the passage of a modern commitment law. That his efforts did not succeed may be ascribed to the whims of the inevitable congressman who in every session appeared to block him, usually only with the argument that "they don't do things that way where I come from." When his bill finally does become law it is to be hoped that its authorship is acknowledged.

It would be hard to overestimate the value of the more than 35 years' service of Dr. White to this association. Always interested and active he could be depended upon to answer any demand. On committees and in the Council he showed, in his consideration of the affairs of the association, both wisdom and a rare judgment. In the clinical sessions he was a most highly valued discussant. How many times he rose to his feet to discuss some particularly troublesome, difficult or obscure point, to defend some policy or some clinical or scientific trend of thought from attack I do not know. They were many. And invariably the atmosphere was the clearer when he sat down. Of the many occasions that come to mind one may be referred to—that occasion at the meeting in Baltimore in 1914 when certain

of the older members to whom the word psychoanalysis was anathema made a concerted and bitter attack on this method of approach to the problems of the patient. Dr. White, quite undisturbed, responded, the high effectiveness of his reply being enhanced no less by his simple logic than by his restraint, temperance of speech and obvious good humor.

In his Presidential address delivered at the Richmond, Va., meeting in 1925, Dr. White argued for a union of the various associations then existing whose interests were common with those of The American Psychiatric Association. Those associations, among others mentioned at that time, included the National Association for the Study of Epilepsy and the American Association for the Study of the Feebleminded. He there laid the foundation for our present sectional organization, without loss of essential independence of the various parts but united and the more powerful for the carrying out of our common aims.

He was a prolific writer. We cannot dwell here on this aspect of his activities. Eighteen books came from his pen, two of them, Modern Treatment of Nervous and Mental Disease, and Diseases of the Nervous System, a textbook of Neurology and Psychiatry, in collaboration with his friend Jelliffe. With Dr. Jelliffe also he published the Nervous and Mental Disease Monographs and the Psychoanalytic Review, the latter dating from 1913.

His Outlines of Psychiatry, for more than 30 years the textbook of the medical student, went through 14 revised editions and was published in many foreign languages. There are included in his bibliography well over 200 published works.

With his singular lucidity of thought and expression he was always, to many of us, the great interpreter and integrator. He influenced, I believe, more than anyone else, the incorporation of psychiatry into general medicine. This is evidenced today by our medical school curricula. It would be difficult indeed to estimate how much he did to remove general lightness of view on the part of medical men toward psychiatry.

To the public at large he interpreted with great clarity the principles of mental hygiene. He was one of the earliest of those who recognized and wrote of the contributions which should flow in either direction between psychiatry and the social sciences. More effectively than any other man he sought to integrate psychiatry with law for the benefit of the mentally ill.

Many have wondered how so busy a man could be so productive. With an article to prepare he studied and wrote late at night, he discussed the subject with whomever might be close at hand. He formulated his subject matter in his mind and then he dictated rapidly, pacing up and down the floor, his hands behind him, and rarely did he make a correction. With such a task before him he was most impatient. He felt driven until it was completed. With dictation finished he hung restlessly over his secretary's shoulder asking from time to time as to progress being made until the typing was done.

He was a great speaker; his presence, quality of tone and enunciation, logic, simplicity in verbal selection and gift for analogy made it a delight

to hear him. He was a remarkable extemporaneous speaker. To his formal addresses he gave much thought and preparation.

He was naturally in great demand. He talked before medical societies, scientific associations, legal groups, social workers, nursing associations, lay bodies about the subjects nearest his heart.

He overtaxed his strength again and again. His intimate friend Jelliffe says tersely, "Had he been less conscientiously strenuous and less ready to respond to every call made on him we would have had him with us many more years." That may be true but who in looking back would deny the great constructive value of his message or *deny him* the happiness of having done his duty as on innumerable occasions the opportunity came to him?

At a time when the significance of psychiatry was growing so rapidly, when new roads were opening up on every hand, when the influence of psychiatric thought and effort was spreading with disconcerting speed in so many unforeseen directions, such a man—someone articulate—was needed, and William A. White was there. He brought with him clarity of thought, calm and considered argument, wise counsel.

Dr. White was appointed Professor of Nervous and Mental Diseases at the Medical School of Georgetown University almost immediately after assuming his duties at St. Elizabeth's. In 1904, a year later, he became Professor of Psychiatry at George Washington University. He also lectured each year to members of the Army, Navy and Public Health Medical Corps. In the minds of those who listened to his lectures and case presentations there was never a doubt as to his greatness as a teacher.

The many important positions he held testify to the appreciation and acclaim of his fellows. He was a former President of The American Psychiatric Association; a member of the Board of Directors of the National Committee for Mental Hygiene; former President of the International Committee for Mental Hygiene; and presided at the First International Congress for Mental Hygiene held in Washington in 1930. He was a former president of the American Psychopathological Association; of the Society of Nervous and Mental Diseases of the District of Columbia; a Fellow of the American College of Physicians; a Fellow of the American Medical Association; a member of the American Institute of Criminal Law and Criminology; the American Neurological Association; American Anthropological Association; and many other learned societies and associations.

Dr. White married in March, 1918, Mrs. Lola Thurston, widow of Senator Thurston, of Nebraska, a lady of great charm in whose circle of friends he had been included almost from the time of his coming to Washington. Her influence and help during those early years was important to him and the devoted companionship which ensued greatly enriched his life.

He was a shy man though he concealed it. He was modest, unassuming and given to self-questioning. To one or two who were very close to him he would say sometimes, "I wonder if I am accomplishing anything?" There has rarely been a man who was more sensitive than he to the unhappiness or misfortunes of others. He did not care for vacations. Work

was his greatest pleasure. He did enjoy student gatherings, smokers and those meetings with groups of friends where men relax and put away for the moment everything serious. There his laughter rang out and his happiness was contagious. He had a fine sense of humor and his conversation was wholesomely pungent. He was a good friend and to his friends gave of himself lavishly.

He was to have been the speaker at a dinner to a friend of 30 years' close association. He was not at all well but felt that he must go. He attended but before he was called on to speak he suffered a chill and was taken home. He did not get up again. Six days later the end came.

Finally, may I quote from his presidential address at the First International Congress on Mental Hygiene: "Mental hygiene presents a positive program for life well lived. . . . . The value of life is measured by what we become and so by the nature of the influences we radiate in our living. Life's values are . . . . expressed in terms of character of man as a social being, of those effects he produces on those about him, the enthusiasms he stimulates, that go reverberating down the ages, translated by the personalities that trace back to the original source. . . . . This is a tangible form of immortality toward which everyone may strive with some show of success and, in the striving, get out of life the most there is in it for him."

Quite unconsciously he here spoke of himself, his life's work and its unending influence.

PRESIDENT CAMPBELL.—In accordance with precedent, I shall now ask the President-Elect, Dr. Chapman, to take the chair.

President-Elect Chapman assumed the chair.

CHAIRMAN CHAPMAN.—It is with the greatest of pleasure that I introduce to you our President, Charles Macfie Campbell!

President Campbell read his presidential address, following which the audience arose and applauded.

CHAIRMAN CHAPMAN.—The presidential address is, as you know, not open to discussion, but I am assured that in this instance you will approve of my calling on Dr. Adolf Meyer to express our appreciation of this splendid presentation.

DR. ADOLF MEYER.—*Mr. Chairman, Dr. Campbell and Members and Guests of the Association:* We have listened to a verbal picture of peace and war, of wide ranges of detail and of the opportunity which all of us have in our share in the problem that brings us together, namely, the opportunity of seeing wholes and parts, large ranges and intimate details. It is that, to my mind, which was a fitting picture for what activates us the days of this week. I liked the realization of our program being widely diversified, very detailed, and the need of having in the presidential introductory address a setting for that which is first furnished us, for that which will activate a great deal of our time and of our interest.

Undoubtedly those who brought forth the recommendation for peace, the psychiatrists who activated a large number of psychiatrists to speak for the concept of something apparently too peaceful, where peace is connected with the idea of absolute quiet—those who had that in mind certainly were people of action, were people who had an interest in bringing that which seems not to express all the instincts before the people who, after all, are activating the wide range of life of the world. We can do but very little; but whether we go to the details of chemistry, to the details of physiology, to the details of the nervous system, to the details of behavior, we ultimately have to find the settings. I am delighted to hear particularly the emphasis on the picture of the person who in the institution which gives us a concentration of the many cases has to find that balance which will bring the knowledge of detail into the life of the institution, the life of those about the institution and the life of that which I think has more and more come to constitute our definition of psychiatry.

I thank Dr. Campbell for giving us this setting for the cafeteria.

CHAIRMAN CHAPMAN.—Thank you, Dr. Meyer.

Now, sir, I restore the meeting to your hands.

President Campbell resumed the chair.

PRESIDENT CAMPBELL.—This is the end of this morning's program, so a movement to adjourn is in order.

The meeting adjourned at eleven fifty-five o'clock.

WEDNESDAY MORNING SESSION.

MAY 12, 1937.

The meeting convened at nine-forty o'clock, President Campbell presiding.

PRESIDENT CAMPBELL.—The meeting will please come to order.

The first piece of business this morning is the report of the Council. Dr. Sandy!

SECRETARY SANDY.—The Council met in the William Penn Hotel, Tuesday, May 11, 1937, at 5.15 p. m. Dr. Campbell, the President, presided. There were 16 members present.

Invitations for the 1938 meeting were further considered from Detroit, Mich.; Cincinnati, and Columbus, Ohio; Chicago, Ill.; and again from San Francisco, Calif.; members of the association representing these several cities presenting their invitations in person. A secret ballot indicated a majority of the members favored San Francisco, Calif.

Upon motion of Dr. Grill, seconded by Dr. Williams, the Council then voted unanimously to hold the 1938 meeting in San Francisco, Calif., the time to be fixed by the Executive Committee after conferring with the local Committee on Arrangements.

The Council discussed the report of the Committee on Public Education, suggesting to the Chairman, Dr. Burlingame, that further consideration be given it for reference again to a subsequent meeting of the Council.

In the absence of the Chairman, Dr. Strecker, the Secretary read the revised report of the Committee on Psychiatry in Medical Education. Upon motion of Dr. Cheney, seconded by Dr. Williams, the Council voted to accept the report for printing in the proceedings with the deletion of the third paragraph.

Upon motion of Dr. Hamilton, seconded by Dr. Jackson, the Council voted approval of the following resolution:

"In case a Fellow or Member has been dropped for non-payment of dues and asks for reinstatement, he shall be required to submit evidence that all arrears to the Association have been paid. If the Board of Examiners shall recommend his reinstatement, a former Fellow may elect to pay also the dues paid by Fellows during the intrevening years in order that he may hold his eligibility for life membership."

The Council adjourned at 6.35 p. m.

PRESIDENT CAMPBELL.—What is your wish with regard to this report of the Council?

DR. HARRY STACK SULLIVAN.—I move the report be received and approved.

The motion was seconded and carried.

PRESIDENT CAMPBELL.—The report of the Auditors will be postponed until a subsequent meeting.

I call upon the Chairman of the Nominating Committee for the report of the Nominating Committee. Dr. Cheney!

DR. CHENEY.—Mr. President, in accordance with the ballot that has been forwarded to all members of the Association, the Nominating Committee proposes for election the following Fellows of the Association:

For President for the year 1937-38, Dr. Ross McC. Chapman, Towson, Md.

For President-Elect, Dr. Richard H. Hutchings, Utica, N. Y.

For Secretary-Treasurer, Dr. William C. Sandy, Harrisburg, Pa.

For Councillors for three years:

Dr. Charles Macfie Campbell, Boston, Mass.
Dr. Charles H. Dolloff, Concord, N. H.
Dr. George S. Johnson, San Francisco, Calif.
Dr. Harry C. Solomon, Boston, Mass.

For Auditor for three years, Dr. Robert B. Winterode, Crownsville, Md.

PRESIDENT CAMPBELL.—Nominations from the floor are in order. If there are no nominations from the floor, what is your wish with regard to this report of the Nominating Committee?

DR. HARRY STACK SULLIVAN.—I move the Secretary be instructed to cast one ballot for the election of the nominees for the positions stated.

The motion was seconded and carried.

PRESIDENT CAMPBELL.—Mr. Secretary!

SECRETARY SANDY.—I hereby cast the ballot.

PRESIDENT CAMPBELL.—The Secretary has cast the ballot, and the officers for the coming year are:

President, Dr. Ross McC. Chapman, Towson, Md.
President-Elect, Dr. Richard H. Hutchings, Utica, N. Y.
Secretary-Treasurer, Dr. William C. Sandy, Harrisburg, Pa.
Councillors for three years
Dr. Charles Macfie Campbell, Boston, Mass.
Dr. Charles H. Dolloff, Concord, N. H.
Dr. George S. Johnson, San Francisco, Calif.
Dr. Harry C. Solomon, Boston, Mass.
Auditor for three years, Dr. Robert P. Winterode, Crownsville, Md.
Is there any unfinished business, Mr. Secretary?

DR. SECRETARY.—There is none.

PRESIDENT CAMPBELL.—Is there an new business?

The meeting adjourned at ten forty-five o'clock.

THURSDAY MORNING SESSION.

MAY 13, 1937.

The meeting convened at nine-forty o'clock, President Campbell presiding.

PRESIDENT CAMPBELL.—The meeting will please come to order.

The first piece of business is the presentation of the Auditor's report. Dr. Buckley!

DR. BUCKLEY.—*To the Members of The American Psychiatric Association:* On behalf of the Auditors, I would respectfully present the following statement concerning the accounts and receipts and expenditures of The American Psychiatric Association for the period from April 16, 1936, to April 15, 1937, also the statement of the cash receipts and disbursements for the AMERICAN JOURNAL OF PSYCHIATRY for the period of April 16, 1936, to April 15, 1937, which accounts have been examined by Turoff & Goldstock, Certified Public Accountants, we have checked the vouchers and balances and find them correct.

ALBERT C. BUCKLEY,
MAX A. BAHR,
JULIAN W. ASHBY.

PRESIDENT CAMPBELL.—What is your wish with regard to this Auditors' report? Does anyone move its acceptance?

DR. BRILL.—I so move.

The motion was seconded and carried.

PRESIDENT CAMPBELL.—The next piece of business is with regard to the election of members. You have each before you a list of members which has been carefully gone over by the Board of Examiners who referred the names on this list to the Council, who again went over this list and who recommend these candidates for the various forms of membership which you will see on the mimeographed list.

There are 31 candidates recommended for Associate membership, 159 for Membership. There are 12 recommended for transfer from Associate Membership to Membership, and there are 11 recommended for transfer from Membership to Fellowship. What is your wish with regard to these names?

DR. CORIAT.—I move the Secretary cast one vote for the entire list.

The motion was seconded and carried.

PRESIDENT CAMPBELL.—Mr. Secretary, will you please cast the ballot?

The Secretary cast the ballot.

PRESIDENT CAMPBELL.—The Secretary having cast his ballot, these members are duly elected.

MEMBERS ELECTED MAY 13, 1937.

ASSOCIATE MEMBERS.

Baganz, Crawford Norbert, M. D., Lyons, N. Y.
Birnbaum, Leo, M. D., Sheridan, Wyoming.
Bondar, H. Kelliher, M. D., New York City, N. Y.

PRESIDENT CAMPBELL.—Have you any further business, Mr. Secretary? Is there any business to be brought up from the floor?

The meeting adjourned at nine forty-five o'clock.

FRIDAY MORNING SESSION.

MAY 14, 1937.

The meeting convened at nine-forty o'clock, President Campbell, presiding.

PRESIDENT CAMPBELL.—The Association will please come to order. The first piece of business is the report of the Council by the Secretary.

SECRETARY SANDY.—The Council met in the William Penn Hotel at 5.10 p. m., Thursday, May 13, 1937, Dr. Campbell, the President, presiding. There were 12 members in attendance.

The Council voted to accept the revised report of the Committee on Public Education for printing in the proceedings.

The revised report of the Committee on Psychiatric Social Work was also accepted subject to such possible minor changes as may be deemed necessary by the President.

The Secretary read a communication from the Royal Medico-Psychological Association, transmitted to the President by the Secretary of the British Embassy, inviting the appointment of delegates of The American Psychiatric Association to the annual meeting to be held at Ayr, Scotland, from July 7 to July 8, 1937. The Council authorized the President to designate as delegates members who may find it possible to attend the meeting of the British Medico-Psychological Association.

The Council nominated to the American Board of Psychiatry and Neurology:

Dr. Adolf Meyer.
Dr. C. Macfie Campbell.
Dr. Franklin G. Ebaugh.
Dr. Edward A. Strecker.

The Council tendered Dr. Cheney a vote of thanks for his services in connection with the organization and continued activities of the American Board of Psychiatry and Neurology.

Upon motion of Dr. Chapman, seconded by Dr. Cheney, the Council approved the appointment of Dr. William E. Gardner, of Louisville, Ky., to the Board of Examiners to succeed Dr. Campbell, whose term has expired.

The Council voted the nomination of Dr. John C. Whitehorn, of Waverly, Mass., to represent the Association on the National Research Council to succeed Dr. Farr, whose term has expired.

The Council elected the Executive Committee to consist of the officers:

Dr. Ross McC. Chapman, President.
Dr. Richard H. Hutchings, President-Elect.
Dr. William C. Sandy, Secretary-Treasurer.

and two other members:

Dr. J. Allen Jackson.
Dr. Walter L. Treadway.

The Council passed a resolution of thanks to President Campbell for the inspiration of his leadership and his effective conduct of the affairs of the Association during the past year.

The Council adjourned at 6.15 p. m.

PRESIDENT CAMPBELL.—What is your wish with regard to this report? Are there any topics that come up for discussion or any questions to be asked?

DR. BRILL.—I move you, sir, the report be adopted as read.

The motion was seconded and carried.

The meeting adjourned at nine forty-five o'clock.

FRIDAY AFTERNOON SESSION.

MAY 14, 1937.

The meeting convened at twelve forty-five o'clock, President Campbell presiding.

PRESIDENT CAMPBELL.—I should like to call on the Chairman of the Committee on Resolutions to present the resolutions. Dr. Stevenson!

Dr. George H. Stevenson read the report of the Resolutions Committee.

PRESIDENT CAMPBELL.—The report of the Committee on Resolutions is accepted with acclamation.

I shall now call upon Dr. Brill to introduce the incoming President.

DR. A. A. BRILL.—*Mr. President, Ladies and Gentlemen:* As I sat here in the beginning of the meeting and listened to Dr. Ross McClure Chapman giving his eulogizing address on the death of his former collaborator and friend, Dr. William Allanson White, I said to myself, "What an admirable and befitting tribute Dr. Chapman gave to an aristocrat of our organization."

Whatever the word "aristocrat" connotes, we understand it as someone who has maintained himself for a long time in a group and not only lived up to the ideals of that group, but progressively carried on the standards of the organization.

As I ruminated in this way, it occurred to me that a great many of the virtues that Dr. Chapman used in the characterization of Dr. White were embodied in himself. It was not, naturally, strange to feel that way, because Dr. Chapman and Dr. White were intimate friends, whereas originally they were in the relationship of teacher and pupil and the pupil became a friend, which means that there was a definite acceptance of an original father and an identification with him.

Dr. Chapman went through a steady and progressive activity in psychiatry. He started in 1906 in the Utica State Hospital. It is remarkable that the Utica State Hospital which is the oldest state hospital in New York, is giving us the incoming President, the President-Elect, Dr. Hutchings, who has been superintendent of it for about 15 years, and an ex-President, another active organizer and standard-bearer of this organization, Dr. Cheney.

Dr. Chapman spent 10 years in his own state, in the State of New York, when he was called as first assistant physician to St. Elizabeth's by Dr. White. To obtain a position of this kind, Dr. Chapman had to show a definite character as a scientist and an organizer.

From Washington, Dr. Chapman then was chosen to take the superintendency of the Sheppard and Enoch Pratt Hospital where he has been functioning since as a steady and sympathetic encourager of science in every effort to help mental and emotional disturbances.

I cannot fail to mention here that Dr. Chapman, like a great many others here, was so sympathetic when I first brought psychoanalysis before this organization, which at that time met with so much resistance. Dr. Chapman has continued for 31 years as a psychiatrist of note. He has done excellent work in his own state. He has worked for the nation, made a splendid record in his work and is a well-known teacher. If we are to judge the future by the past, which we psychiatrists usually do, I feel it augurs well for this organization to have as our incoming President Dr. Ross McClure Chapman, and I take great pleasure in introducing him to you.

PRESIDENT CAMPBELL.—Might I ask Dr. Overholser and Dr. Haskell to act as a guard of honor and escort the President to the platform, according to the traditions of this Association?

Drs. Overholser and Haskell escorted the newly elected President, Dr. Chapman, to the platform.

PRESIDENT CAMPBELL.—Mr. President, it is my very pleasant duty to present to you the insignia of office. I regret that the insignia has a somewhat somber appearance, but you will have to look upon it as conveying to you not merely a badge of office but conveying to you the respect and affection of your colleagues. I am sure that you will find the members of this Association at your service and foremost among those who will be at your service is myself who have been your friend and colleague for over 30 years.

President Chapman took the chair.

PRESIDENT CHAPMAN.—First, I must thank my good friend, my ancient friend, Dr. Brill, not for his too fulsome praise, but for the masterly manner in which he handled a very, very difficult situation.

As I stand here, you see, I feel very strange indeed. I feel a great deal of loss and a good deal as if I were in a dream. I think I feel perhaps more humble than anything else. I have no illusions as to my capacities. There are a great many men who would make a better President in this Association. Here centers something of the fortuitous. Here chance enters as it does in medical associations at times. The lightning strikes here and it strikes there and sometimes it strikes in the most surprising places.

I do not wish to make any lengthy speech. I want to assure the Association of my profound appreciation, of my gratitude for the honor that has been conferred upon me. I want to pledge to the Association my most earnest efforts for the year to come.

Next year the meeting is in California. We go to new fields. Within an hour or so after the meeting place had been chosen, the Program Committee was at work thinking of the special problems that possibly might arise in a meeting at that distance. It is their wish, I know, and it is the wish of all of us, that the California meeting be a success, and if it can be made half as successful as this splendid meeting presided over by Dr. Campbell which is coming to a close has been, we should all be very happy indeed.

So I ask your help, I ask your participation and cooperation because without that the administration of this year on which we are entering cannot be successful. I am sure that I will have such cooperation.

The pleasantest duty that I have or that I will have during the coming year falls to me to perform at the present moment. That is to bestow on the outgoing President the medal or badge of the Association which is known as the badge of the Past President. The Past President—I think that is a dreadful name. I suppose that Dr. Campbell feels that now the burden has rolled from his shoulders, that he can go back to Boston and renew the teaching of the young and play golf and enjoy his tea and a nap perhaps after lunch, that there is no more, that his work for this Association has ended. That, very fortunately, is not the case. If you will look about you and see Dr. Cheney sitting here, Dr. Russell back of him, Earl Bond and one or two others here

who have been Past Presidents, you will realize, Dr. Campbell, that this is only your introduction to hard work. Do not deceive yourself. This badge is a deceiving thing which merely means that you are about to enter into the new types of service and in a sense the Association from now on will work itself well knowing that you are quite helpless and must be so.

It gives me a great deal of pleasure to have the opportunity of bestowing this badge on you. With it there goes the affectionate esteem of the entire Association, the gratitude of the entire Association, and particularly of the officers, Councillors, committeemen and so forth, who have worked with you during the past year. The splendid program is your work; the success of this splendid meeting is yours.

It gives me great pleasure, sir, to extend this to you.

DR. CAMPBELL.—I wish to express my thanks to the Association for this badge which entitles me to inclusion among the club of the passé, and I wish to take this opportunity of thanking the Association individually and collectively for their constant help during the past year. I wish to thank the officers of the Association and Dr. Chapman. I especially wish to thank the Secretary-Treasurer who was the guide of my infant footsteps and who kept me in the straight and narrow path, psychiatrically speaking, during the past year.

Thank you very much!

PRESIDENT CHAPMAN.—Mr. Secretary, is there anything further?

SECRETARY SANDY.—Nothing further.

PRESIDENT CHAPMAN.—I, therefore, then declare the ninety-third meeting of The American Psychiatric Association closed.

The meeting adjourned at one o'clock.

WILLIAM C. SANDY, M. D., *Secretary-Treasurer.*

PROCEEDINGS SCIENTIFIC SESSION

OF THE

NINETY-THIRD ANNUAL MEETING

OF THE

AMERICAN PSYCHIATRIC ASSOCIATION

MAY 10-14, 1937, PITTSBURGH, PA.

JOINT SESSION SECTION ON CONVULSIVE DISORDERS AND AMERICAN CHAPTER OF INTERNATIONAL LEAGUE AGAINST EPILEPSY.

MONDAY MORNING, MAY 10, 1937.

Dr. Stanley Cobb presiding.

Introductory Remarks by Chairman Cobb.

Interpretation of the Electrical Activity of the Brain, by Dr. Hallowell Davis.

Epilepsy: A Paroxysmal Cerebral Dysrhythmia, by Drs. F. A. Gibbs, E. L. Gibbs and W. G. Lennox. Discussion by Dr. Max Levin.

Electrical Signs of Cortical Function in Epilepsy and Allied Disorders, by Drs. Herbert H. Jasper and Ira C. Nichols. Discussion by Dr. William G. Lennox.

The Histopathology of Convulsive Disorders in Children, by Dr. H. M. Zimmerman. Discussion by Drs. Charles Davison, Herbert H. Jasper, Charles P. Fitzpatrick, Adolf Meyer, Stanley Cobb and H. M. Zimmerman.

Motion Picture shown b Dr. Dan S. Renner. Discussion by Dr. William W. Graves.

MONDAY AFTERNOON, MAY 10, 1937.

Dr. Cobb presiding at first, later Dr. W. G. Lennox.

The Cost of Institutional Care of Epileptics in Massachusetts, by Drs. Douglass V. Brown and Merrill Moore. Discussion by Drs. Theodore Diller, Morgan B. Hodskins, Neil A. Dayton, Dan S. Renner, William G. Lennox and Douglass V. Brown (closing).

The Use of Intravenous Methylene Blue in Status Convulsivus, by Drs. Laslo Kajdi and Charles V. Taylor. Discussion by Drs. Stanley Cobb, Theodora Wheeler, Laslo Kajdi, Hugo Mella and Laslo Kajdi (closing).

A Study of the Mentality of Dispensary Epileptic Patients, by Drs. Margaret R. Barnes and Joseph L. Fetterman. Discussion by Drs. Robert L. Dixon, William G. Lennox and J. L. Fetterman (closing).

Some Clinical Neurological Findings in Epilepsy, by Drs. Samuel W. Weingrow, Thomas S. P. Fitch and Albert W. Pigott. Discussion by Drs. Erwin Wexberg and Theodora Wheeler.

Results of Fifteen Years' Experience with the Ketogenic Diet in the Treatment of Epilepsy in Children, by Drs. Henry F. Helmholz and Moe Goldstein. Discussion by Drs. Stanley Cobb, J. L. Fetterman, Morgan B. Hodskins, William W. Graves, William G. Lennox and Henry F. Helmholz.

Report of Nominating Committee.

MONDAY EVENING, MAY 10, 1937.

Dr. G. Kirby Collier presiding.

Remarks on History of the National Association for the Study of Epilepsy, the international League, etc.

The Campaign Against Epilepsy, by Dr. William G. Lennox. Discussion by Drs. Adolf Meyer, Morgan B. Hodskins, Stanley Cobb, William G. Lennox, Robert L. Dixon and Solomon Katzenelbogen.

SECTION ON FORENSIC PSYCHIATRY, MONDAY MORNING, MAY 10, 1937.

Dr. V. G. Branham presiding.

Phylobiological Aspects of Forensic Psychiatry, by Dr. Hans Syz.

Cultural Factors in Crime, by Dr. Franz Alexander. Discussion by Dr. Gregory Zilboorg.

Psychological Interrelationship Between Suicides and Homicides, by Dr. Gregory Zilboorg.

Results and Conclusions Concerning the Warwick School Management of Young Male Delinquents, by Dr. Frederick Tilney. Discussion by Drs. Clarence Oberndorf, A. A. Brill, Bernard Glueck, Charles F. Menninger, Erwin Wexberg and J. L. McCartney.

MONDAY AFTERNOON, MAY 10, 1937.

Dr. V. G. Branham presiding.

The Community's Responsibility Toward Crime, by Judge Paul N. Schaffer. Discussion by Dr. Winfred Overholser.

Borderline Mental States in Crime, by Dr. David B. Rotman.

A psychiatric Study of Recidivists, by Dr. Charles B. Thompson.

A Psychologic Study of the Swindler, by Dr. Walter Bromberg. Discussion by Drs. Karl M. Bowman and Franz Alexander.

Modus Operandi and Psychopathology of Homicides and Sex Offenders, by Dr. John A. Larson.

SECTION I. TUESDAY AFTERNOON, MAY 11, 1937.

President Campbell presiding.

Primary Affect Hunger, by Dr. David Levy.

Child Analysis as a Technique in the Investigation of Mental Mechanisms, by Dr. Margaret W. Gerard.

Child Psychiatry, by Dr. James S. Plant.

Some Therapeutic Principles Applicable to Psychiatric Work with Children, by Dr. Frederick H. Allen.

An Evaluation of the Treatment of Problem Children as Determined by a Follow-Up Study, by Drs. Howard W. Potter and Henriette R. Klein.

Problem Children Growing Up, by Dr. Leo Kanner. Discussion by Drs. James K. Everhart, Adolf Meyer, Erwin Wexberg, James L. McCartney, David M. Levy (closing), Margaret W. Gerard (closing), Frederick H. Allen (closing) and Leo Kanner (closing).

JOINT SESSION WITH SECTION ON PSYCHOANALYSIS AND THE AMERICAN PSYCHOANALYTIC ASSOCIATION. WEDNESDAY MORNING, MAY 12, 1937.

President Campbell at first presiding, later Dr. Hutchings acting as chairman.

Psychoanalytic Contributions in Private Psychiatric Practice, by Dr. George W. Smiltz.

The Psychoanalytic Clarification of Personality Types, by Dr. Ernest E. Hadley.

Psychoanalytic Contributions to the Conception of Disorder Types, by Dr. N. Lionel Blitzsten. Discussion by Drs. A. A. Brill, Nolan D. C. Lewis, Harry Stack Sullivan, Gregory Zilboorg, M. Ralph Kaufman, Clarence P. Oberndorf, Henry M. Hart, A. A. Brill and Jacob Kasanin.

WEDNESDAY AFTERNOON, MAY 12, 1937.

Dr. C. F. Williams at first presiding, later Dr. Earl D. Bond.

Prognosis in Mental Disease, by Drs. Earl D. Bond and Francis J. Braceland. Discussion by Drs. William W. Graves, Ross Dodson, Bernard Glueck and Francis J. Braceland.

The Irganic Background of Obsessions and Compulsions, by Dr. Paul Schilder. Discussion by Drs. Harold F. Corson, Erwin Wexberg and Paul Schilder (closing).

Bio-Physical Factors in Relation to Functional Imbalance, by Dr. Trigant Burrow. Discussion by Drs. Helen P. Langner and Trigant Burrow (closing).

Parotid Gland Secretions in Manic-Depressive Patients, by Drs. Edward I. Strongin and Leland E. Hinsie. Discussion by Drs. Roy D. Halloran, P. G. Hamlin, Eugene S. Falstein and Edward I. Strongin (closing).

Relations Between Precipitating Situations and Outcome in Manic-Depressive Psychosis, by Dr. Robert C. Hunt. Discussion by Drs. Grace Baker and Robert C. Hunt (closing).

JOINT SESSION WITH AMERICAN PSYCHOLOGICAL ASSOCIATION,
THURSDAY MORNING, MAY 13, 1937.

Dr. Lewis presiding.

Presidential Address by Dr. Nolan D. C. Lewis.

Factors in Character Development, Neuroses, Functional Psychoses and Delinquency, by Dr. Margaret E. Fries. Discussion by Drs. Gregory Zilboorg, Spurgeon English, A. A. Brill and Margaret E. Fries (closing).

The Location of the Conflict Situation: An Orientation to the Problem of Delinquency, by Dr. Sidney Tarachow. Discussion by Drs. Isador H. Coriat, Eugen Kahn, David M. Levy and Sidney Tarachow (closing).

Hyperthyroidism and Personality, by Drs. Warren T. Brown and Edwin F. Gildea. Discussion by Drs. Fred P. Currier, Eugen Kahn, William L. Nelson, John A. P. Millet, Nolan D. C. Lewis and Warren T. Brown (closing).

The Experimental Neurosis and the Problem of Mental Disorder, by Dr. H. S. Liddell. Discussion by Drs. Thomas M. French and H. S. Liddell.

JOINT SESSION WITH THE SECTION ON MENTAL DEFICIENCY,
THURSDAY AFTERNOON, MAY 13, 1937.

Dr. R. H. Haskell presiding.

Psychotic Symptoms and Outcome of 1388 Cases Observed at the Walter E. Fernald State School, by Dr. Ransom A. Greene. Discussion by Drs. Thomas P. Brennan, Groves B. Smith, Neil A. Dayton, William W. Graves and Ransom A. Greene.

The Significance of Special Reading Disability in Mentally Handicapped Problem Children of Higher Grade, by Dr. G. Hegge. Discussion by Drs. Marion Monroe, Leo Kanner, Joseph Zubin and G. Hegge (closing).

The Appraisal of Intellectual and Physical Factors After Cerebral Damage in Children, by Drs. Bronson Crothers and Elizabeth Lord. Discussion by Drs. Groves B. Smith, Lloyd J. Thompson, Max H. Weinberg, Oscar J. Raeder, Robert H. Haskell and Bronson Crothers (closing).

Habeas Corpus Releases of Feebleminded Persons and Their Consequences, by Dr. Leo Kanner.

Development of Family Care in New York State, by Dr. Hiram G. Hubbell. Discussion by Dr. Kenneth B. Jones, Miss Hester B. Crutcher and Dr. Leo Kanner.

FRIDAY MORNING, MAY 14, 1937.

President Campbell presiding.

The Psychiatric Manifestations of Hypoglycemia, by Drs. Edwin J. Kepler and Frederick P. Moersch.

The Methodical Use of Hypoglycemia in the Treatment of Psychoses, by Dr. Manfred Sakel. Discussion by Dr. John R. Ross.

Experience with the Hypoglycemia Treatment of Schizophrenia, by Drs. Solomon Katzenelbogen, Herbert Harms and Dean A. Clark.

Further Experiences at Bellevue with the Hypoglycemia Insulin Treatment of Schizophrenia, by Drs. Joseph Wortis, Karl M. Bowman, Leo L. Orenstein and Irvin J. Rosenbaum.

Experience with the Hypoglycemia Shock Treatment of Schizophrenia, by Drs. G. Alexander Young, Richard H. Young and L. Roucek. Discussion by Drs. Bernard Glueck, Henry J. John, Julius Steinfeld, Gert Heilbrunn and Manfred Sakel (closing).

SECTION II. STUDIES ON HABITATION, TUESDAY AFTERNOON, MAY 11, 1937.

President-Elect Chapman presiding.

Personality and Sociological Factors in the Prognosis and Treatment of Chronic Alcoholism, by Drs. Kenneth J. Tillotson and Robert E. Fleming. Discussion by Drs. James J. Waygood, Gregory Zilboorg, Theodore Diller and Kenneth J. Tillotson.

Alcoholism and the Psychoneuroses, by Dr. William B. Terhune. Discussion by Drs. Fred Adams, Frank Curran and William B. Terhune.

Vitamin "C" Studies in Alcoholics, by Drs. Herman Wortis, S. Bernard Wortis, and Frances Marsh. Discussion by Drs. Edward E. Mayer, Stanley Cobb and Herman Wortis.

Clinical Studies of Drug Addiction: A Critical Review of the Withdrawal Treatments with Method of Evaluating Abstinence Syndromes," by Drs. Lawrence Kolb and C. K. Himmelsbach. Discussion by Drs. Walter Bromberg, Robert S. Carroll and Lawrence Kolb.

The Symptoms and Treatment of Barbital Intoxication, by Dr. Frank J. Curran. Discussion by Drs. Max Levin and Frank J. Curran.

BRAIN PATHOLOGY, WEDNESDAY MORNING, MAY 12, 1937.

Dr. J. Allen Jackson at first presiding, later Dr. Walter L. Bruetsch.

The Histopathology of the Psychoses with Subacute and Chronic Endocarditis, by Dr. Walter L. Bruetsch. Discussion by Drs. Fernand Longpre, Adolf Meyer and Walter L. Bruetsch.

Hereditary Form of Primary Parenchymatous Atrophy of the Cerebellar Cortex Associated with Mental Deterioration, by Dr. Andrew J. E. Akelatitis. Discussion by Drs. Adolf Meyer, David Rothschild and Andrew J. E. Akelaitis.

Defects of Intelligence Resulting from Lesions Within the Central Part of the Left Cerebral Hemisphere, by Dr. Leland B. Alford. Discussion by Drs. Charles Englander, Raymond C. Fagley, William Nelson and Leland B. Alford.

Circumscribed Cortical Atrophy in the Presenile Psychoses—Pick's Disease, by Dr. Charles Davison. Discussion by Drs. David Rothschild, Lloyd J. Thompson, Max H. Weinberg and Charles Davison.

Mental Changes Following Removal of the Right Cerebral Hemisphere for Brain Tumor, by Dr. Stuart N. Rowe. Discussion by Drs. Lloyd J. Thompson and Stuart N. Rowe.

JOINT SESSION ON PSYCHOANALYSIS AND THE AMERICAN PSYCHOANALYTIC ASSOCIATION, WEDNESDAY AFTERNOON, MAY 12, 1937.

Dr. R. H. Hutchings presiding at first, later Dr. Coriat in the chair.

Observations of Primitive Reactions in New Born Infants, by Dr. Margaretha Ribble. Discussion by Drs. Isador H. Coriat, A. A. Brill, Lawrence S. Kubie and Margaretha Ribble.

The Fantasy of Dirt, by Dr. Lawrence S. Kubie.

Remarks About the Relation of Inferiority Feeling to Guilt Feeling, by Dr. Franz Alexander.

Folie à Deux as a Clinical Picture and in Normal Life, by Dr. Helene Deutsch.

The Sense of Immortality, by Dr. Gregory Zilboorg. Discussion by Drs. David C. Wilson, Franz Alexander, George S. Sprague, Lawrence S. Kubie and Gregory Zilboorg.

HOSPITAL AND EXTRA-MURAL PROBLEMS, THURSDAY MORNING, MAY 13, 1937.

Dr. Winfred Overholser presiding.

Educational Functions of the Present Day Mental Hospital, by Dr. Arthur H. Ruggles and Dr. Charles P. Fitzpatrick. Discussion by Drs. William Nelson, Ira M. Altshuler, W. Scott Farmer, Gilbert Seaman and Arthur H. Ruggles.

Present Crisis in Social Relationships, by Dr. Samuel W. Hartwell. Discussion by Drs. George S. Stevenson, George Van Ness Dearborn and Samuel W. Hartwell.

A Constructive Criticism of Certain Hospital Procedures, by Karl M. Bowman. Discussion by Drs. Arthur P. Noyes, A. H. Braverman, Theodore Diller and Ira M. Altshuler.

Nursing Education, by Miss May Kennedy. Discussion by Dr. George H. Stevenson, Mr. Rowden and Miss May Kennedy.

Pre-Admission Care and Methods of Transfer of Psychotic Patients, by Dr. W. M. Bevis. Discussion by Drs. W. Scott Farmer, H. Curtis and W. M. Bevis.

THERAPEUTIC PROCEDURES, THURSDAY AFTERNOON, MAY 13, 1937.

President-Elect Chapman presiding at first, Dr. Titus H. Harris later.

Six Years' Experience with Narcosis Therapy in Psychiatry, by Dr. Harold D. Palmer and Dr. Francis J. Braceland. Discussion by Drs. Frederick L. Patry, Mary G. Schroeder, W. L. Moore, Harry A. Schneider, Julius Steinfeldt and Harold D. Palmer.

Treatment of the Psychoneuroses at Stockbridge, by Dr. Austen Fox Riggs and Dr. Gaylord P. Coon. Discussion by Drs. Harry M. Tiebout, Frederick J. Farnell, Theodore Diller and Isador H. Coriat.

Bibliotherapy and Mental Disorders, by Dr. William C. Menninger. Discussion by Drs. Merrill Moore, John E. Lind, Isador H. Coriat and William C. Menninger.

Paresis: An Analysis of Five Hundred and Eleven Treated Cases, by Drs. Robert A. Matthews, Robert S. Bookhammer, and William H. Izlar. Discussion by Drs. Francis J. Braceland and Meyer K. Amdur.

Influence of Calcium on Behavior, by Dr. Robert W. Robb. Discussion by Drs. Bettina Warburg, Theodora Wheeler and Robert W. Robb.

SECTION ON MENTAL DEFICIENCY, FRIDAY MORNING, MAY 14, 1937.

Dr. Oscar J. Raeder at first presiding, later Dr. R. H. Haskell.

The Differences in the Mental Reactions Between Children Suffering from Cerebral and from Cerebellar Tumors, by Dr. Leo M. Davidoff. Discussion by Drs. Max H. Weinberg and Leo M. Davidoff.

A Clinical Guide to the Study of Personality, Character and Behavior in Human Defectives, by Dr. Edward J. Humphreys. Discussion by Dr. Oscar J. Raeder.

Emotional Differences in Colored and White Inmates in a School for the Feeble-minded, by Dr. James Lewald. Discussion by Drs. S. L. Cohen and James Lewald.

The Relation Between Mental Level and Endocrine Disorders, by Dr. Matthew Molitch. Discussion by Drs. Hugh T. Carmichael, Robert H. Haskell and Matthew Molitch.

Heredity and Environment in Relation to the Mental Defective, by Dr. Jacob Sirkin. Discussion by Drs. James Lewald and Jacob Sirkin.

SECTION III. STUDIES FROM THE LABORATORY,
TUESDAY AFTERNOON, MAY 11, 1937.

Dr. J. Allen Jackson presiding.

Significance of Brain Potentials in Relation to Potentials in the Spinal Cord and Peripheral Nerve, by Drs. Edward A. Strecker, Joseph Hughes and Kenneth E. Appel. Discussion by Drs. David R. Clark, Edward A. Strecker, Herbert Jasper and Joseph Hughes (closing).

Sugar Content of the Blood and Cerebrospinal Fluid in Various Psychotic States, by Drs. E. P. Johns and G. H. Stevenson. Discussion by Drs. J. F. Bateman, Solomon Katzenelbogen, G. H. Stevenson and E. P. Johns (closing).

Kline Microprecipitation Reactions with Spinal Fluid, by Dr. Irving M. Derby. Discussion by Drs. Michael A. Burns and Irving M. Derby (closing).

Cerebrospinal Fluid Pressure in the Psychoses, by Dr. H. Beckett Lang. Discussion by Drs. James F. McFadden and H. Beckett Lang (closing).

The Irritative Therapy of Schizophrenia, by Dr. Emerick Friedman. Discussion by Drs. Myer K. Amdur, Solomon Katzenelbogen, Robert S. Carroll, Charles F. Read, G. H. Williams, S. W. Hartwell and Emerick Friedman (closing).

CLINICAL STUDIES, WEDNESDAY MORNING, MAY 12, 1937.

Dr. Oskar Diethelm presiding.

Studies in Obsessive Ruminative Tension States V. Etiology, Dynamics and Genesis of Psychasthenia, by Dr. Lawrence F. Woolley. Discussion by Drs. Frederick L. Wright and Lawrence F. Woolley (closing).

Post-Puerperal Psychoses, by Dr. Louis J. Karnosh. Discussion by Drs. John P. Powers, Erwin Wexberg and Louis J. Karnosh (closing).

The Arm-to-Carotid Circulation Time in the Mental Diseases, by Dr. Jacques S. Gottlieb. Discussion by Drs. Louis J. Doshay, Solomon Katzenelbogen, J. E. Finesinger, Louis J. Doshay and Jacques S. Gottlieb (closing).

Post-Operative Psychoses, by Dr. Milton M. Abeles. Discussion by Drs. Joseph L. Gilbert, George J. Wright, Louis J. Doshay, David R. Clark and Milton M. Abeles (closing).

Psychoses from Nutritional Deficiency, by Dr. Erwin Wexberg. Discussion by Drs. Siegfried Block and Erwin Wexberg (closing).

THERAPY. WEDNESDAY AFTERNOON, MAY 12, 1937.

Dr. G. H. Stevenson presiding.

The Psychiatrist's Roles with His Patients, by Dr. George S. Sprague. Discussion by Drs. Henry Harper Hart, Oscar Diethelm and George S. Sprague (closing).

One Hundred Years of Non-Restraint, by Dr. E. Messinger. Discussion by Drs. Henry L. Klopp and E. Messinger (closing).

A Socialization Program in the Treatment of Dementia Præcox, by Dr. O. R. Yoder. Discussion by Drs. Ernst L. Bagby, Ira Altshuler, Hugh S. Gregory, Frederick L. Wright and O. R. Yoder (closing).

Mental Reactions and Their Management in Patients with Cardiac Disease, by Drs. James H. Wall and Patrick H. Drewry. Discussion by Drs. Dexter M. Bullard, Frank Luton, Clarence O. Cheney and Patrick H. Drewry (closing).

Occupational Therapy in Facilities of the Veterans Administration, by Dr. Orren P. Goodwin. Discussion by Drs. Fred C. Smith and Richmond Berk.

CLINICAL PATHOLOGICAL STUDIES. THURSDAY MORNING, MAY 13, 1937.

Dr. Robert C. Woodman presiding.

Huntington's Chorea: A Genealogical Study of Two Families, by Drs. A. Lindenfeld and Max Rossman. Discussion by Drs. Percy R. Vessie and Eugene I. Falstein.

Psychoses with Cerebral Arteriosclerosis: A Clinicopathologic Study, by Dr. David Rothschild. Discussion by Drs. Naomi Raskin, Arthur P. Noyes, Jacob Kasanin and H. W. Williams.

Correlations of Behavior and Neuropathology in a Case of Cerebral Palsy from Birth Injury, by Dr. Arnold Gesell. Discussion by Drs. Bronson Crothers and Arnold Gesell (closing).

Clinicopathologic Considerations for Differential Diagnosis Between Juvenile Paresis and Other Forms of Encephalitis, by Drs. A. Ferraro, S. E. Barrera and H. S. Gregory. Discussion by Drs. Coyt Ham and Diomede Guertin.

Pathological Physiology of Acute Insanity, by Dr. S. DeWitt Ludlum. Discussion by Drs. Albert C. Buckley and S. DeWitt Ludlum (closing).

OPEN MEETING OF AMERICAN PSYCHOPATHOLOGICAL ASSOCIATION.

THURSDAY AFTERNOON, MAY 13, 1937.

Dr. Nolan D. C. Lewis presiding.

Experimental Study of Conceptual Thinking in Schizophrenia, by Dr. Jacob Kasanin. Discussion by Drs. Eugen Kahn, Paul Schilder, Gregory Zilboorg, George S. Sprague and Jacob Kasanin (closing).

The Interpersonal Element in Schizophrenic Thought, by Dr. Hiram K. Johnson. Discussion by Dr. Harry Stack Sullivan.

Parental Conflicts in Relation to Children, by Dr. Gregory Zilboorg. Discussion by Drs. David C. Wilson, Sarah R. Kelman, Erwin Wexberg and Gregory Zilboorg (closing).

Flight from Reality Through Loss of Sense of Personal Identity—Depersonalization, by Dr. Cornelius C. Wholey. Discussion by Drs. B. C. Schiele, Clarence P. Oberndorf, Paul Schilder, Eugen Kahn and Cornelius C. Wholey (closing).

The structure and Origin of the Delusion, by Dr. Fritz Kant. Discussion by Drs. Paul Schilder, George S. Sprague, L. H. Horton, Eugen Kahn, Fritz Kant (closing) and L. H. Horton.

FRIDAY MORNING, MAY 14, 1937.

Dr. L. N. Ziegler presiding.

Cardiovascular Disease in Neuropsychiatric Patients, by Dr. Bennie A. Moxness. Discussion by Drs. Nolan D. C. Lewis, Walter Bruetsch, Emanuel Messinger and Bennie A. Moxness (closing).

A Value of "Free Association," in State Hospital Practice, by Dr. Morris W. Brody. Discussion by Drs. William W. Elgin, Leo Kanner, L. N. Ziegler, Joseph Zubin, G. H. Preston, John D. Benjamin and Morris W. Brody (closing).

The Clinical Value and Diagnostic Reliability of the Rorschach Test, by Drs. John D. Benjamin, Franklin G. Ebaugh. Discussion by Drs. Joseph Zubin and John D. Benjamin (closing).

Psychopathological Effect of Adrenalin and Mecholyl on Patients in States of Anxiety, by Drs. Erich Lindemann and J. E. Finesinger. Discussion by Drs. Harry Stack Sullivan, John D. Benjamin, L. N. Ziegler, Joseph Zubin, George F. Southerland and Erich Lindemann (closing).

A Psychiatric Study of Carsickness in Children, by Dr. Jacob H. Conn. Discussion by Drs. Charles W. Stephenson, Erich Lindemann and Jacob Conn (closing).

ROUND TABLE DISCUSSIONS.

THURSDAY EVENING, MAY 13, 1937.

CHILD PSYCHIATRY.

Moderator: Dr. David M. Levy.
Discussants: Drs. David Slight, George S. Stevenson, Norvelle C. Lamar (by invitation), and Samuel W. Hartwell.

OCCUPATIONAL THERAPY.

Moderator: Dr. C. Charles Burlingame.
Discussants: Drs. Earle V. Gray, William Rush Dunton, Jr., Frank F. Tallman, Mrs. Eleanor C. Slagle (by invitation), and Miss B. Nelson (by invitation).

PSYCHIATRIC NURSING.

Moderator: Dr. George H. Stevenson.
Discussant: Mae Kennedy, R. N.

PSYCHOANALYSIS: ERRONEOUS ATTITUDES CONCERNING THE RÔLE OF SEX IN PSYCHOSES AND PSYCHONEUROSES.

Moderator: Dr. Leland E. Hinsie.
Discussants: Drs. A. A. Brill, J. Benjamin, Louis Casamajor, Isador H. Coriat, Helene Deutsch (by invitation), Paul Schilder and Lloyd H. Ziegler.

PSYCHIATRIC PRIVATE PRACTICE.

Moderator: Dr. Leslie B. Hohman.
Discussants: Drs. Bernard Glueck, Roger S. Cohen, W. W. Young, Theodore Diller, Grace Baker, Edward E. Mayer and Siegfried Block.

PSYCHOSOMATIC RELATIONSHIPS.

Moderator: Dr. H. Flanders Dunbar.
Discussants: Drs. M. Ralph Kaufman, Robert B. McGraw, Clarence P. Oberndorf, Karl A. Menninger, William Menninger, Franz Alexander and George Wilson.

SCIENTIFIC METHOD IN PSYCHIATRY.

Moderator: Dr. Jacob Kasanin.
Discussants: Drs. Adolf Meyer, Nolan D. C. Lewis, E. Morton Jellinek (by invitation), Stanley Cobb, John C. Whitehorn and Gregory Zilboorg.

THE VETERANS ADMINISTRATION.

Moderator: Dr. Appleton H. Pierce.
Discussants: Drs. George Van Ness Dearborn, Noble D. Leonard and others.

TUBERCULOSIS IN MENTAL HOSPITALS.

Moderator: Dr. Henry L. Klopp.
Discussant: Dr. George Clair Brink (by invitation).

FORENSIC PSYCHIATRY. CRIMINALITY.

Moderator: Dr. Vernon C. Branham.

1. Dr. Eugene Davidoff—"The Development of Clinics in Hospitals or in University Out-Patient Departments as a Means of Service to Delinquents."
2. Dr. Frederick H. Allen—"Clinics in Connection with Children's Court Work."
3. Dr. James McCartney—"The Use of Travelling or Itinerant Child Guidance Clinics as a Service to Courts in the Rural Districts."
4. Dr. Paul Schroeder—"The Functioning of Psychiatric Clinics in Courts Handling Adult Delinquency."
5. Dr. Matthew Molitch—"The Use of Parole Clinics for the Examination of Delinquents."

HYPOGLYCEMIA.

Moderator: Dr. Bernard Glueck.

WILLIAM C. SANDY, M. D., *Secretary-Treasurer.*

REPORTS OF COMMITTEES.

The following reports of Committees and of the Secretary-Treasurer were presented to the Association and approved by it during the convention sessions in Pittsburgh, Pennsylvania, May 10 to 14, 1937.

Report of the Executive Committee.

Following the personal investigation of hotel facilities in Pittsburgh by the Secretary and Executive Assistant and upon their recommendation, the Executive Committee selected the William Penn Hotel at Pittsburgh for the 93d annual meeting and the time May 10 to 15, 1937.

The Executive Committee met at the Hotel Commodore, New York, 2.30 p. m., December 28, 1936, all members being present.

The question of designating the place and time of meeting of the Association two years in advance in order to insure satisfactory arrangements as to the hotel, program and so on was generally discussed but no action taken, the subject to be considered later by the Council.

The Secretary recommended the establishment of a trust fund for the conservation of the finances of the Association. The Executive Committee upon motion of Dr. Overholser, seconded by Dr. Chapman, voted to recommend to the Council the consideration of the establishment of a trust fund and a study of the various kinds of trust fund that might be desirable, for report at a May, 1937, meeting.

Upon the motion of Dr. Chapman, seconded by Dr. Overholser, the Executive Committee voted to recommend to the Council that Austin M. Davies be continued another year as Executive Assistant and that his salary be increased to $3600 per annum.

The Executive Committee also voted to recommend to the Council to increase the salary of Miss Dorothy Rubenstein, stenographer-clerk at the New York office of the Association, to $1350 per annum.

The Secretary suggested increasing the dues of members to $7 annually, at present there being no distinction between members and associate members, the dues of both classes being $5. The committee decided to recommend to the Council that the dues of members be made $7.

The committee adjourned at 3.45 p. m.

The Council met at the Hotel Commodore, New York, at 3.45 p. m., December 28, 1936, there being 22 members present. President Campbell in the Chair.

The Chairmen of the various committees submitted preliminary statements.

Dr. Cheney, of the Board of Examiners, reported progress, there being at present 121 applications for membership.

Dr. Hall of the Program Committee stated that 70 papers have already been offered, there being time at the St. Louis meeting for about 50. There will be on one afternoon a symposium on "What child psychiatrists gain as experience of value to psychiatrists in general." All sections except that on mental deficiency have been contacted and the program arrangement will be similar to that of last year. Round tables have been suggested on the following subjects: Suicide, the scientific method in psychiatry, tuberculous patients in mental hospitals, physiological manifestations of psychobiological reactions, psychoanalysis, alcoholism, and Veterans Administration problems. Dr. Breutsch will as usual have charge of the scientific exhibits. Upon inquiry, Dr. Hall was advised that the Council approved arranging for a discussion of hypoglycemic shock treatment of dementia præcox.

Dr. Burlingame of the Committee on Public Education briefly reviewed the accomplishments in controlling the publicity of the St. Louis meeting and the efforts to promote public information. He asked for a ruling as to permitting the press to use graphs and charts. The Council referred Dr. Burlingame to the decision at the St. Louis meeting at which it was voted that "subject to the confirmation that such a procedure is the practice of the American Medical Association, the Committee on Public Education is authorized to give to the press copies of charts and illustrations with the consent of the authors of the papers," leaving the question within these limitations to the decision of the Chairman of the committee.

Dr. Frederick, on Arrangements, reported the plans of his committee with particular reference to the entertainment of members and guests. Included are a fashion show and bridge party, a luncheon and sightseeing trip for the ladies and special features for the evening banquet.

Dr. Farr, of the Committee on Research, discussed the geographical index of research projects, analysing subjects by locality. He also called attention to Dr. Breutsch's activities in arranging for the scientific exhibit. A member of the committee has suggested four possible responsibilities to be assumed by the Committee on Research, *i. e.* (1) to act as advisers on anticipated research problems; (2) to suggest topics for research; (3) to read manuscripts critically; (4) to indicate what funds or endowments might be available. Dr. Farr reported that he has received numerous statements covering the work of the National Research Council but he has found nothing of interest to the Association which he had not previously communicated.

Dr. Dayton, of Nomenclature and Statistics, favored continuation of the nomenclature in use about two years although there has been criticism of the section on psychoneuroses. He asked consideration of three points:

1. There are at present three classifications (a) psychoses and other mental conditions as used by the mental hospital group; (b) those used by the epileptic group; (c) and a third as used by the mental deficiency group.

2. At present, there is no separation in the statistical tables of first and readmissions in discharge and death compilations.

3. There should be closer cooperation between the Association and the Bureau of Census in the selection of statistics to be published.

Upon motion of Dr. Cheney, seconded by Dr. Overholser, the Council voted approval of Dr. Dayton's suggestion that the mental deficiency and epileptic classifications now in use by those groups be included in the psychiatric classification.

The Council, after further favorable discussion of the recommendations of the Chairman of the Committee on Nomenclature and Statistics, authorized Dr. Dayton to consult with the Director of the Bureau of the Census at Washington and the payment of the necessary expenses of this trip.

Dr. Stevenson, of the Committee on Psychiatric Nursing, stated that no new applications for certification of training schools had been received and expressed the opinion that there will probably be a further reduction in the number of schools. This is not a discouraging sign but an indication of such higher standards as staffing with graduates or the establishment of post graduate or affiliated courses. Dr. Stevenson requested advice as to (1) publication of Miss Bailey's report without deletion; (2) new standards for nursing schools, the same to refer to future applicants; (3) should the committee secure data from all states and provinces as to schools giving postgraduate and affiliated courses.

In the discussion which followed, the consensus of opinion appeared to be in favor of the publication of Miss Bailey's report as written with no names of institutions to be mentioned.

The Council voted, upon motion of Dr. Cheney, seconded by Dr. Chapman, that the Committee on Psychiatric Nursing be authorized an expense of not more than $100 for the purpose of securing information from all states and provinces as to nursing schools giving postgraduate and affiliated courses.

Dr. Tyson, on Ethics, reported progress.

Dr. Noyes, Standards and Policies, stated that at a meeting of his committee to-day, three subjects were considered: First, the geographical distribution of mental patients in institutions as compared with the membership of the Association as submitted by Dr. Treadway. The committee suggests the desirability of taking steps to increase the membership in regions not now well represented. Second, the question of some action in view of the subversive political activities in Massachusetts. Third, the mental hospital survey. The committee feels that psychiatrists to be detailed for service in the survey should be of first assistant grade and that the honorarium should be $15 per day with expenses.

After much discussion, the Council, upon motion of Dr. Hamilton, seconded by Dr. Cheney, took the following action in regard to the Massachusetts situation.

The Council discussed and deplored the recent disregard of psychiatric standards in Massachusetts which ignored the needs and rights of the mentally ill and handicapped and which tended to disorganize their care in Massachusetts and directed the Executive Committee to draft a suitable resolution.

The Council approved the suggestion that the usual honorarium for psychiatrists serving in the survey shall be $15 per day and travel expenses, those detailed to be of not less than the first assistant or assistant superintendent grade with more compensation in special instances.

Dr. Overholser, Legal Aspects of Psychiatry, discussed the suggestion of the committee that much more could be accomplished if funds could be secured from some foundation to make possible the full time services of a secretary for the compilation of information and other activities.

Upon motion of Dr. Cheney, seconded by Dr. Brill, the Council authorized Dr. Overholser to approach some foundation for the purpose of securing funds for the use of his committee.

The Council adjourned 6.30 p. m. for dinner. At 8.30 p. m. the Council resumed.

Dr. Hartwell, on Psychiatric Social Service, requested suggestions as to the scope of his committee and the objective of the report. He was advised that the report is to the Council, that it should be not too long but a clear and uncomplicated discussion of phases of social service as it relates to psychiatry. Long dissertations should be left for papers on the subject for presentation at some session of the Association.

In the absence of the Chairman, Dr. Ebaugh reported progress for the Committee on Psychiatry in Medical Education.

Dr. Farrar, Editor, announced that Dr. Nathaniel Brush has donated to the Association the file of the JOURNAL belonging to the late Dr. Edward N. Brush, which dates from 1844, to be for the use of the Editor. Owing to the increasing burden of gratuitous service on the Editorial Board, Dr. Farrar raised the question as to desirability of the annual appointment to the board. The Editor announced that arrangements have been made with Science Service in Washington to publish as monographs selected lengthy articles such as are published from time to time and which are too long for the JOURNAL, the Association to be given credit, and placing them on sale.

Dr. Farrar asked advice as to continuing the printing of discussions of papers.

The Council voted that the Editor be given full authority of editing and deciding whether or not discussions shall be printed.

The Council also voted that the members of the Editorial Board be appointed annually.

The Council directed the Secretary to express appreciation to Dr. Nathaniel Brush for the gift of the file of the AMERICAN JOURNAL OF PSYCHIATRY for the use of the Editor.

Dr. Buckley reported for the auditors that in their opinion, it is, under present circumstances, unnecessary for the Secretary-Treasurer to be bonded. No recommendation was made as to possible desirable change in the places of depository.

The Secretary read the resolution of the Executive Committee as to the establishment of a trust fund, after which, on motion of Dr. Hamilton, the Council approved the suggestion, referring the question of a trust fund to the Executive Committee for investigation and report at the May meeting.

The question of selecting the time and place of meeting of the Association two years in advance aroused much discussion. The Council finally adopted the suggestion of Dr. Hamilton, seconded by Dr. Buckley that beginning in

1937 for 1939 requests for designation of a city or a region as the place of meeting of this Association shall be submitted in writing not later than November first of the second year preceding the meeting.

Upon motion of Dr. Jackson, seconded by Dr. Williams, the Council approved the reappointment of Austin M. Davies as Executive Assistant for one year, his salary to be $3600 per annum.

Dr. Williams then moved, Dr. Brill seconded, and the Council voted to increase the salary of Miss Dorothy Rubenstein, stenographer-clerk to $1350 per annum.

The Council voted to remit the dues and to accept the resignations of Dr. Reginald S. E. Murray, Gardner, Mass., and Dr. Frank C. Richmond, Madison, Wisc., at their request, on account of serious illness.

The Secretary reported that word had been received from Dr. Henry B. Ward, Permanent Secretary of the American Association for the Advancement of Science that The American Psychiatric Association has been accepted as an affiliated Society with an invitation to send a representative to the Atlantic City meeting this week.

The Secretary was instructed to write to the Permanent Secretary of the American Association for the Advancement of Science that on account of the short notice, the Association was unable to designate a representative for the Atlantic City meeting.

The Council adjourned 10.50 p. m.

At subsequent conferences of members of the Executive Committee the following resolution was prepared and later approved by mail by all members of the Committee:

Resolution.

At the direction of the Council of The American Psychiatric Association, the Executive Committee prepared the following resolution in reference to the situation in Massachusetts:

"Deep concern is felt over the recent appointments in Massachusetts. The best interest of the mentally sick and handicapped and of their distressed families can only be served when those in authority encourage continuity of service and insist on recognized professional qualifications and breadth of experience.

In order that such a policy prevail, steps should be taken to make the real issues clear to those in authority and to the general public.

Be It Therefore Resolved, That the Editor of THE JOURNAL insert in an early number an editorial dealing with the situation.

Be it also resolved to bring the situation to the attention of the National Committee for Mental Hygiene in order that constructive steps be taken for the maintenance of those high standards of care of the mentally sick and handicapped in Massachusetts which have given Massachusetts for so long an enviable position among the states.

Respectfully submitted,

C. MACFIE CAMPBELL, M. D., *Chairman,*
Executive Committee.

Report of the Secretary, 1936-37.

WILLIAM C. SANDY, M. D., *Treasurer.*

April 19, 1937.

Mr. Austin M. Davies, Executive Assistant, American Psychiatric Association, 2 East 103rd Street, New York City.

DEAR SIR:

As per your request, we have made an examination of the books and records of The American Psychiatric Association and of the AMERICAN JOURNAL OF PSYCHIATRY.

We present herewith the following statements which are in agreement with the books and reflect the cash transactions for the period under review.

*1. State of Cash Receipts and Disbursements for The American Psychiatric Association for the period April 16, 1936, to April 15, 1937.

*2. Statement of Cash Receipts and Disbursements for the AMERICAN JOURNAL OF PSYCHIATRY for the period April 16, 1936, to April 15, 1937.

*3. Schedule of Bank Balances and Cash Resources.

In connection with our audit of your records, we reconciled all bank statements, added all footings, analyzed cash receipts and disbursements and examined all vouchers.

Should you desire any additional information upon any item in this report, please do not hesitate to call upon me.

Respectfully submitted,

TUROFF AND GOLDSTOCK.

By A. A. TUROFF,

Certified Public Accountant.

---

* NOTE.—These statements were used as the basis for the report of the Treasurer and appear in the foregoing report as submitted by the Certified Public Accountant.

Report of the Executive Assistant.

Your Executive Assistant herewith respectfully submits his annual report:

It is my pleasant duty to report that the past year was one of growth, the office accounts showing for the first time a favorable balance. There was a net increase of 71 in the membership with comparatively few delinquents in dues; there being 75 Fellows, 61 Members and 6 Associate Members still unpaid.

Although overhead was increased by salary raises and appropriations to the Mental Hospital Survey Committee, both the Association and the JOURNAL accounts have satisfactory balances.

Since May, 1936, we have secured 80 new subscriptions to the JOURNAL, of which 47 were the result of a special drive in December. The total number of subscriptions is now 543, which is a net increase of 40 since last May.

I am happy to report that all the commercial exhibit space for the Pittsburgh meeting was sold and will yield approximately $1,235.00.

Advertising revenues have also been satisfactory, receiving $1,728.24 from renewals and $492.00 in new contracts, an increase of $142.87 over 1936.

Your Executive Assistant has again cooperated in assisting the Secretary, the Board of Examiners, the Committee on Arrangements and the Committee on Program.

An attempt is being made to collect historical material of the Association and the JOURNAL. Contributions of this nature will be welcomed.

REPORT.

April 16, 1936–April 15, 1937.

INCOME		
New Business and Renewals		
New Subscriptions (80)	$ 480.00	
Renewal of Subscriptions	2,778.00	
New Advertising ($327.00 still due)	492.00	
Renewal on Advertising ($638.55 still due)	1,728.24	
Commercial Exhibits (May 1936)	800.00	
Total		$6,278.24
DISBURSEMENTS		
Office Expense		
Rent of Office	$ 900.00	
Telephone and Telegraph	200.76

Printing (letterheads, envelopes, etc.)	123.73	
Dorothy Rubenstein—Salary	1,243.75	
Austin M. Davies—Salary	3,150.00	
Total		$6,138.84

Very truly yours,

AUSTIN M. DAVIES.

REPORT OF COMMITTEE ON STANDARDS AND POLICIES.

At the 1922 meeting of the Association held at Quebec the following resolution was adopted:

"Whereas, The American Psychiatric Association is interested in securing the highest possible standards for the care of the mentally ill,

"*Be it Resolved,* That a permanent Committee on Standards and Policies shall be appointed by the President by and with the consent of the Council. . . . .

"It shall be the duty of this committee to prepare an annual report in relation to standards and policies regarding the treatment of the mentally ill."

The constructive work performed by this first committee under the chairmanship of Dr. W. L. Russell is well known to the Council and the Association. After a survey which was as extensive as was possible in the absence of funds necessary for the personal inspection of institutions the committee formulated the familiar outline of minimum standards that should be attained by an institution in order to be considered properly qualified for the care of mental patients. In an editorial discussion of this painstaking report the JOURNAL in the issue for October, 1924, commented: "When the work outlined in the report is undertaken it will require the expenditure of a vast amount of time and energy on the part of those having it in charge, and there must be available a considerable sum of money to meet the expense of the study of hospitals and hospital methods and personnel involved." Since the publication of the first report of the Committee on Standards and Policies subsequent reports of the committee have contained various recommendations as to surveys which should evaluate and promote the resources and agencies devoted to the institutional care of the mentally disabled. They have also contained discussions as to governmental policies and types of organization that tend to promote or to impair the quality of medical and psychiatric care. While recognizing that any approach to the problem of mental disorders, their prevention and enlightened treatment should be a much broader one yet it seemed that a survey of mental hospitals, with special reference to the standards of care and treatment of their patients, was the most urgent need and the only one for which funds might reasonably be expected to be available. It is with great satisfaction, therefore, that through the generosity of the Rockefeller Foundation and the cooperative association of the major national organizations and agencies interested in the subject, an exhaustive and critical study, not only of hospital administration and function, but also of the facilities of psychiatric institutions for under-graduate and graduate teaching and for research as well as of public policies pursued in dealing with this important medical, social and health problem has now been made possible. Editorial comments in the issues of the JOURNAL for September, 1936, and January, 1937, describe the organization and indicate the initial aims and activities of the Mental Hospital Survey Committee, the official body created to represent the various participating agencies.

It will be recalled that at its 1936 meeting the Association appropriated $5000 to be paid as honoria and as traveling expenses to members of the

Association assisting in the survey. In recent months one of the important duties of the Committee on Standards and Policies has been the preparation, in association with the Director of the Mental Hospital Survey Committee, of a list of members who might be qualified and available for institutional surveys in various regions. Unfortunately in not a few instances the demands of other duties made it impossible for particularly qualified members to accept assignments. It is a source of much satisfaction, however, that Dr. H. O. Colomb was able to devote a period of six weeks to a survey of hospitals in the South. His wide experience in mental hospitals and his acquaintance with that region rendered him particularly qualified. At the time of the writing of this report Dr. Colomb is the only physician engaged in surveying institutions whose expenses have been paid from Association funds. It is expected, however, that other surveys will soon be begun by psychiatrists jointly selected by the committee and the Director of the Mental Hospital Survey Committee.

On several occasions in recent years the Committee on Standards and Policies has referred to the pernicious influence of politics as they affect the care and treatment of mental patients. Although in several instances it has come to the attention of the committee that political influences were preventing the establishment of desirable standards of institutional care yet it refrained from mentioning any specific state where this was true. At a meeting of the Committee on Standards and Policies held in New York, December 28th, there was extended discussion concerning the removal for political reasons of two prominent Massachusetts psychiatrists possessing outstanding qualifications for the responsible administrative positions they occupied. In a preliminary report submitted to the Council on the same day the committee requested an expression of opinion as to the advisability of specific mention in its annual report concerning the deplorable change of policy in Massachusetts. The Council indicated its approval and then directed its Executive Committee to draft a resolution expressing concern over recent exercises of gubernatorial power which, it was believed, disregarded psychiatric standards and tended to disorganize the care of the mentally ill and handicapped in that state. Since this resolution and extended discussion concerning the subject are published in the January, 1937, issue of the JOURNAL in an editorial comment entitled "Serious Political Situation in Massachusetts," further presentation by the Committee on Standards and Policies of the wanton disregard of those principles which had formerly placed Massachusetts in an enviable position of leadership in the care of its mentally disabled is scarcely required.

REPORT OF THE COMMITTEE ON LEGAL ASPECTS OF PSYCHIATRY, 1936-37.

The Committee on the Legal Aspects of Psychiatry respectfully presents its annual report:

A meeting of the committee was held in New York City in December, 1936, and the Chairman has been in touch with the members during the year, both by correspondence and personally. The committee has been hampered somewhat in its activities by the fact that so far it has found it impossible to arrange a meeting (such as has usually been held annually) with the Committee on Psychiatric Jurisprudence of the American Bar Association. An informal meeting of a representative of this committee with a member of the Bar Association and American Medical Association Committees was held last summer, however, when plans were briefly discussed.

In its report for 1936, the Committee on Psychiatric Jurisprudence proposed a continuing research into the actual extent of the application of psychiatry in the determination of the disposition of the offender. Your committee agrees heartily with this recommendation, and is of the further opinion that a corollary of this activity might well be the collection and dissemination of information regarding actual and desirable legal provisions as well as concerning medico-legal literature. Indeed, the publication at regular intervals of a critical survey of the developments and possibilities in the interrelated fields of criminology and psychiatry might well be considered. At the December meeting, the Council authorized the chairman to request from one of the foundations a subsidy for this purpose. It was estimated that with the sum of about $15,000 a permanent secretary could be employed, who could carry on such activities under the guidance of the committee. It was hoped that the American Bar Association would join in this request, since they made a similar proposal in 1930. Owing to certain technicalities, however, their consent has not yet been obtained, so that the formal application has not been made. The establishment of a permanent bureau of this sort would enable the committee to be of considerable assistance to law-drafting and legislative bodies, as was suggested in this committee's report last year. It is to be hoped that the coming year will see the fruition of this plan.

Ten years ago this committee, under the chairmanship of Dr. Karl A. Menninger, presented a report which embodied a "credo" and outlined certain desiderata. Some progress in accomplishing those aims can be recorded, though much remains to do.

During the past year the U. S. Public Health Service, in conjunction with the Department of Justice, established a psychiatric service for certain of the U. S. District Courts. Diplomates of the American Board of Psychiatry and Neurology have been designated as consultants, and are available to advise the court concerning the mental condition of the defendant if such advice is requested by the court. A service of such standards, readily accessible, is almost certain to demonstrate its value promptly and to result in an increased appreciation of the aid which can be rendered by psychiatry to the administration of the criminal law.

The New York State and County Medical Societies and the New York Academy of Medicine, through their committees, are continuing active cooperation with a committee of the New York City Bar Association in attempting to solve some of the perplexing problems relating to medical expert testimony.

Your committee is vitally interested in improvement of the laws relating to the commitment of the mentally ill. In all too many states, antiquated proceedings, savoring of the criminal, are the rule—"lunacy commissions," the requirement of notice to the patient, and even jury trial on the charge of "insanity," are found on the books, and all militate against the humane treatment of the patient and tend to discourage early care. It is especially distressing to note that the most barbarous laws of all are found where progress shold be looked for, namely in the District of Columbia. According to the New York Times for June 29, 1936, a certain congressman who had had the misfortune to develop a psychosis which was brutally advertised by the daily press "was scheduled to appear before a lunacy court—to defend himself against charges that he was dangerous and an 'unfit person to be at large.' The hearing was dismissed upon his transfer to a private hospital." A bill is now pending in Congress (S. 1225) to bring about some slight improvement in the commitment laws of the District. Your committee plans to secure data concerning desirably simple commitment procedures, and possibly to draft a model bill which, while protecting the legal rights of the patient, is humane and progressive.

Very few legislative proposals of interest have come to the attention of the committee. In Oregon (H. 143) a bill proposes to authorize the court to order a party to a case to submit to a mental or physical examination if his mental or physical condition is a matter involved in the case. In Massachusetts (H. 524) a bill to set minimum standards for court-appointed experts in criminal cases was defeated.

The committee has suffered a grievous loss in the death of Dr. William A. White, long an interested and active member. No one in this country has fought more vigorously and effectively for a decent and intelligent attitude toward the mentally abnormal defendant or toward the person in need of commitment than Dr. White. A man of profound erudition and broad human sympathy, he was ever ready to contribute his sage advice on the topics considered by the committee. The psychiatric world has lost a figure of gigantic stature; his like will not soon be seen again.

Respectfully submitted,

REPORT OF THE COMMITTEE ON NOMENCLATURE AND STATISTICS.

To the Council of the American Psychiatric Association:

The committee wishes to bring to the attention of the Association the following four points:

(1) Report of the action of the Bureau of the Census in connection with the separation of the Census statistics on Mental Deficiency and the Convulsive Disorders.
(2) Comment on the more accurate reporting on overcrowding in State Hospitals by the Journal of the American Medical Association.
(3) Suggested change in recommended tables to divide statistics on discharges, deaths and resident population into first and readmissions.
(4) Suggested change to include the clinical classifications of Convulsive Disorders and Mental Deficiency in the present Psychiatric Classification.

(1) The committee reports that the Bureau of the Census accepted the resolve passed by the Council last year in reference to (a) the division of the report on institutions for mental defectives and hospitals for epileptics into two separate sections, and (b) the basing of the newly separated tables in this report upon the clinical classifications of mental deficiency and convulsive disorders, in accordance with the Standard Classified Nomenclature of Diseases. The Bureau cooperated by making the both changes immediately. Beginning with 1936, the publication of the Census Bureau known as "Mental Defectives and Epileptics in Institutions" will be published in two separate sections, one devoted to institutions for mental defectives and the other section to institutions for epileptics. In this way the mixture of classification which characterized early reports will be avoided and a more satisfactory view of nation-wide statistics on these two subjects will be available.

(2) It is gratifying to report that the 1937 Hospital Number of the *Journal of the American Medical Association* has given a much more thorough discussion and treatment of the state hospital situation than in previous years. About eighteen months ago the present chairman of the committee communicated with the *Journal of the American Medical Association* and brought to their attention the serious error which was resulting from their reporting of the "number of beds" in mental hospitals rather than the rated capacity. Past reports recorded a fictitious "under capacity" condition based upon a comparison between the number of beds and the average daily number of patients in institutions. As every institution had a few more beds than patients, this gave the impression that mental hospitals were well within their capacity when, in fact, many of them were greatly overcrowded. This year the JOURNAL statistics included a new item of "Rated Capacity" which immediately revealed the excess of patients in many state hospitals. It is pleasing to note that the 1937 Hospital Number of the *Journal of the American Medical Association* replaces the misleading presentations of former years with an accurate analysis of overcrowding in state hospitals.

(3) Over the past years the official statistics as recommended by The American Psychiatric Association have included a primary division of cases coming into mental hospitals into first admissions and readmissions. However, statistics on discharges, death and resident population have been grouped

without this differentiation. One state (Massachusetts) has made this distinction in its institutional and state-wide statistics. It has been found that when discharges and deaths are divided into first admissions and readmissions, these two subdivisions show differing characteristics. First admissions discharged, for example, are not of the same age composition as readmissions discharged, nor do they show the same proportions of the different psychoses. There is also a distinct difference in the length of hospital stay of first admissions discharged and readmissions discharged. The same is true of the deaths. The resident population shows even more marked differences.

The committee wishes to bring up the question of giving discharges, deaths and resident population the same consideration which is now being given to admissions. The suggestion is made that the statistics of The American Psychiatric Association be revised to include a division of the present tables referring to discharges and deaths into first and readmissions. It is also suggested that the Bureau of the Census be requested to divide its annual statistics on discharges and deaths in this manner, and that its occasional reports on resident population include this same division into first and readmissions. It is felt that a division of our statistics on mental diseases in this manner will make possible a more satisfactory analysis of patients leaving mental hospitals, those dying and those remaining in the resident population. To continue to throw these dissimilar groups together will only continue to cloud our results indefinitely in reference to the matter of outcome.

(4) The use of the new classification of the Standard Nomenclature of Diseases in respect to mental disorders, convulsive disorders and mental deficiency has introduced certain difficulties. The division of the large field of psychiatry into three subdivisions has resulted in the use of three clinical classifications which offer somewhat different descriptions of the same condition. For example, at the present time the mental hospitals classify epileptics in two groups, either "Psychosis with Convulsive Disorders (Epilepsy)" or "Without Psychosis—Epilepsy" while hospitals for epileptics are using the new detailed clinical classification of the Standard Nomenclature. Here we have two different methods of diagnosing convulsive disorders (non-psychotic), all within the same state hospital group. The same is true in mental deficiency. The mental hospitals use the two classifications "Mental Deficiency with Psychosis" and "Without Psychosis—Mental Deficiency," while the state schools are using the detailed classification as outlined by the Standard Nomenclature. Again two sets of state institutions are using two different systems of diagnosis. On the other hand, the hospitals for convulsive disorders and the state schools have tended to use their own clinical groupings without reference to the psychiatric classification. Occasionally, cases diagnosed as "Psychosis with Convulsive Disorders" are found to be schizophrenics. Again, in the state schools, the primary schizophrenia may be undiagnosed and the deteriorated state diagnosed as mental defect. It would be helpful to the medical staffs of both the epileptic hospitals and the state schools if they could have before them the well-defined groupings of the psychiatric classification to aid them in extending the scope and thoroughness of their diagnoses.

At the present time we cannot study the clinical groupings of the convulsive disorders on a state-wide or country-wide basis because of the two different diagnostic procedures in hospitals for epileptics and in mental hospitals. The same is true in the case of mental deficiency, because of the differing diagnostic criteria in mental hospitals and state schools for mental defectives.

A solution to this problem has suggested itself and is being proposed for the consideration of the Association. It is suggested that the clinical classification on epilepsy (pages 502-505 of the Standard Nomenclature) and also the clinical groups in mental deficiency (pages 95-96), with appropriate definitions, be included within the present psychiatric classification. This could be effected by amplifying the present grouping "without psychosis—epilepsy" to include the entire clinical classification of convulsive disorders. In like manner the heading "without psychosis, mental deficiency" would be expanded to include the clinical classification on mental deficiency.

The advantages of such an enlarged classification are immediately apparent. We would have but one system of diagnosis for use in all three types of institutions. The clinical groupings and definitions on the subjects of convulsive disorders and mental deficiency would be easily available to the medical staffs of mental hospitals. This would mean thorough clinical diagnoses on both mental deficiency and convulsive disorders before placement in the proper category. At the same time the availability of the well-defined psychiatric classification would aid the medical staffs of the epileptic hospitals and the state schools for mental defectives in arriving at a better understanding of the psychoses.

The committee wishes to bring to the attention of the Council the problem of a more satisfactory base mental age for the determination of intelligence quotients in adults. For some time opinions have been expressed that the present standard of 16 years is too high and should be reduced to 14 years. Many groups throughout the country have already adopted a 14 or 15 year level and the resulting discrepancies bring the entire matter of the use of the intelligence quotient into disrepute.

It is suggested that the committee study this problem in collaboration with the Section on Mental Deficiency, the American Association on Mental Deficiency and other interested groups, with the thought of determining a uniform standard. Changes deemed desirable will then be recommended to the Standard Classified Nomenclature of Diseases.

Report of the Committee on Psychiatric Nursing.

To the Council of The American Psychiatric Association:

The usual questionnaire was sent to all schools accredited by The American Psychiatric Association. Replies indicate that there is a steady decline in the number conducting undergraduate courses, only 46 being active and admitting students during this year, although several others are completing the education of students already entered. Six schools have discontinued during the year. One school formerly discontinued, resumed activity.

At first glance this might appear unfavorable, but on further inquiry it appears that this decline is more than counterbalanced by an increase in the number of post-graduate and affiliate courses in psychiatric nursing, and is more a reflection of a change in emphasis in the field of nursing education. This is discussed in greater detail later in this report.

The undergraduate schools appear for the most part to be in a fairly healthy condition. During 1936 these schools received 784 students, and graduated 449. All are accredited by their respective State Boards of Nurse Examiners and are complying with adequate standards. Without exception their students have at least a 12 months affiliation in general hospitals for the subjects which cannot be adequately taught in the home school. There is steady improvement in housing, recreation facilities, hours of duty, etc., the most noteworthy advance in this direction being the general adoption of the 48-hour week for both day and night duty in the New York State Hospital system.

The ratio of nursing staff to patients continues to improve, although in many hospitals many more nurses, students and graduates, could be employed to advantage. The lack of nursing staff in the male wards of many hospitals is to be deplored. It should be obvious that sick men need nursing care just as much as sick women. While certain wards in all mental hospitals may not be suitable for women nurses, the use of male nurses on these wards presents no obstacles, and questions pertaining to the training of a sufficient supply of male nurses are being considered by the committee. Certain information concerning nursing schools accepting male students has been elicited by a supplementary questionnaire referred to below.

About half the schools report difficulty in securing suitable applicants. When it is noted that among the 46 schools reporting, there were only 449 graduates, it may be that the difficulty is general and hospital administrators appear to be giving serious consideration to the question whether or not their undergraduate schools should be discontinued. It is noted that the state of Illinois has abandoned its undergraduate course in all its state hospitals.

In an attempt to learn to what extent post-graduate and affiliate courses are available, a supplementary questionnaire was sent to the Secretary of the Board of Nurse Examiners of each state and province. Replies were received from every state and province (with the exception of Utah). The following questions were asked:

1. Names and addresses of hospitals offering post-graduate courses in psychiatric nursing.

2. Names and addresses of hospitals offering affiliate courses in psychiatric nursing.

3. Names and addresses of schools of nursing in other than psychiatric hospitals which give their undergraduate students a course in psychiatric nursing as a part of their basic training, by an affiliation in a psychiatric hospital or through a psychiatric division or ward in the home school.

4. Names and addresses of all hospitals whose schools of nursing accept and train male students.

The replies to these questions are listed below.

Your committee is of the opinion that these figures are encouraging and re-assuring and indicate a definite trend in the direction of making psychiatric nursing a part of the training of all nurses and a definite recognition of the importance of psychiatric nursing. The establishment of a State School of Psychiatric Nursing in Illinois and the appointment of a Director of Psychiatric Nursing for Minnesota, and the real interest shown in the development of psychiatric nursing by many other nurse educators, are indications of the increasing importance and value of such courses.

The fourth question, relating to male nursing, has no direct relationship to the other questions, but was asked in order to give the committee some idea of the facilities which exist at present for the training of male nurses.

The report of the survey conducted by Miss Harriet Bailey, under the joint direction of the National League for Nursing Education and The American Psychiatric Association, was printed in the *American Journal of Nursing* for May, 1936, and reprinted in the JOURNAL of our Association for January, 1937. Your committee is of the opinion that the findings, conclusions and recommendations made are of extreme importance and value for the establishment of better standards of nursing care of the mentally ill and for the education of nurses in this field. Your committee plans to re-consider the standards for schools of nursing accredited by The American Psychiatric Association in the light of Miss Bailey's survey and hopes to make a definite report on standards a year hence.

A conference was held with Miss May Kennedy, Chairman of the Committee on Mental Hygiene and Psychiatric Nursing of the National League of Nursing Education, in December, and Miss Kennedy's offer to present a paper to our Pittsburgh meeting was gratefully received and passed to the Chairman of the Program Committee, which has arranged for it on the program.

Your committee regret the loss of Dr. Chapman as chairman but congratulate him and the Association on his elevation to the office of President-Elect. We are pleased that he continues on the committee and his advice on various occasions has been of great value to us.

All of which is respectfully submitted.

REPORT OF THE COMMITTEE ON PSYCHIATRY IN MEDICAL EDUCATION.

The Committee on Psychiatry in Medical Education is pleased to report continued progress. The committee continues to have the benefit of close and fruitful collaboration with the Division of Psychiatric Education of National Committee for Mental Hygiene. The following information from the files of the division furnishes a perspective concerning the present situation of psychiatry in medical education.

The rating of sixty-eight (68) medical schools would indicate that nineteen (19) give excellent psychiatric instruction, thirty (30) are good in this respect and nineteen (19) are indifferent or poor.

The psychiatric faculty standards were investigated in 68 medical schools in regard to (1) training and experience, (2) number of hours spent in teaching, and (3) productivity. In these points 22 are excellent, 30 good, 16 indifferent to poor.

The average number of hours devoted to the teaching of psychiatry was 76, 48 in 1931-32, and in 1936-37 there was a gratifying increase to 86.9.

In 1932, 32 schools gave preclinical instruction and in 1936 this was raised to 44 schools, being an increase of 37 per cent.

The preclinical courses are designated in various ways: In 19 schools psychobiology; in 15 psychopathology; in 11 medical psychology; in 1 psychiatry; in 1 neuropsychiatry; in clinical psychology; in 3 introduction to psychiatry; in 1 basic human relations; in 2 mental hygiene; in 1 biopsychology; in 1 clinics and lectures on normal and abnormal psychiatry; in 1 psychiatry and mental hygiene; and in 1 general psychopathology. The committee recommends that an attempt be made to standardize the designations of the preclinical courses. The names psychobiology and psychopathology are satisfactory. In any event we feel that the designations of these courses should indicate in some way a relative comparison with the basic medical sciences such as physiology, anatomy and histology and later, a comparison with morbid anatomy and organic pathology.

The appraisal shows that the average number of teachers in the department of psychiatry in 1931-32 was 4.66 and in 1936-37 this average was 7.28.

Clinical facilities were good in 25 medical schools; fair in 21 and inadequate in 22.

The committee is in accord with the recommendations of the Division of Psychiatric Education that there should be greater emphasis on preclinical teaching and that psychiatry should be organized in the teaching curriculum as a separate department.

The committee suggests that every effort be made to increase the amount of psychiatric experience afforded to internes in general hospitals. In this connection, Dr. Henry Christian, of Harvard Medical School, an eminent internist and professor of medicine, has furnished a splendid example.

The committee desires to express its grateful appreciation to one of its members, Dr. Franklin G. Ebaugh, for having borne the labor of fact finding.

Respectfully submitted,

EDWARD A. STRECKER, M. D., *Chairman*,
ADOLF MEYER, M. D.,
FRANKLIN G. EBAUGH, M. D.,
LLOYD H. ZIEGLER, M. D.,
GEORGE S. AMSDEN, M. D.

REPORT OF THE COMMITTEE ON PUBLIC EDUCATION.

Your Committee on Public Education feels more strongly than ever before that the best interests of psychiatry would be served, and a great deal done toward preserving whatever gains we have made, if the Association would enter whole-heartedly into the organizing of a well-equipped, full-time department of public education.

There are specific examples of the value of such an organization as, let us say, the New York Academy of Medicine, and which exercises a potent influence in the community because it has built up a confidence in the press and in the public mind by continued, reliable and temperate educational work. This "good will" if we may call it that, is a valuable asset when the public interest demands that certain situations be clarified by authoritative utterance of a dispassionate, professional group.

The most important and soundest distribution of information concerning mental disease goes into the public through the services rendered to patients and the families, and family physicians. When the physician takes pains to cultivate the language of fact, and translates them into understandable simplicity intelligent conceptions of mental disease can become more prevalent.

At the same time, it is recognized that the press and radio can become conduits through which may flow good educational material, or sensational nonsense, depending upon the source of supply.

In order to interpret and comment on events of a psychiatric nature, particularly those of local interest this Committee believes it would be helpful to have in each region, certain individuals designated with their consent by the Committee for this purpose. While they would not assume to speak for the Association, they would by reason of their standing be in a position to disseminate information in their region. With the approval of the Council, this Committee would make such appointments.

If we are sincere in our belief in the importance of psychiatric principles and the maintenance of high standards, then we must do more than talk about it. We must be willing to take an aggressive stand any time those principles are assailed. If we are not willing to do this, then we should definitely announce ourselves as interested only in the theoretical phases of psychiatry and leave the practical problems to some other organization, medical or otherwise.

But it is not only in this respect that such an active, full-time organization is desirable. Throughout the year, the unsound, the scheming "quack" have access to the public press to announce through paid advertisements or otherwise, "remedies" and "sure cures" for mental ills. These "practical psychologists" and "leading psychoanalysists" as they style themselves are invariably without a medical degree. We should admire their acumen and their practical knowledge that where insufficient sound facts are available, unsound information is easily dispensed. It should be the duty of this Association to see that sound information is disseminated—not periodically, but through its organization, and regional committees, continuously, and through every orthodox medium.

To be effective, such a campaign of education must be affirmative. It is not enough merely to denounce—we must offer a substitute in the way of constructive planning through local and state societies, through regional committees, and through the Association itself.

In these, and many other ways, the Association would contribute to a sound understanding of psychiatry by the public, and by so doing, grow in

stature and strength. As psychiatrists, we know the desirability in human growth of passing on through childhood and adolescence to independent and emancipated adulthood. We believe the same is true of organizations. We are old enough and big enough to be thoroughly matured, but we are dodging our responsibilities in some respects.

Your committee has, in a modest way, made an effort to do some of these things, but we can make no pretense that they have been done adequately, or that they can be done adequately without a properly organized, full-time, day in and day out campaign of public education, with local committees functioning in each region.

The committee has continued to try to foster good relations with the press and it has found the national news agencies not only willing, but eager for authentic information. It is manifestly impossible to reach all local newspapers with our present organization.

We have also tried to cooperate with the Editor of the JOURNAL by collecting news notes from time to time of matters pertinent to psychiatry. We believe this particular section of the Journal could be developed into a useful and informative department through which members of the Association could be made aware of current developments in the national field of psychiatry.

The committee received excellent cooperation from the Committee on Arrangements in setting up facilities for the dissemination of information at the meeting of the Association in St. Louis, and recommend that similar arrangements be made in Pittsburgh this year.

COMMITTEE ON PSYCHIATRIC SOCIAL SERVICE.

The Committee on Psychiatric Social Service on The American Psychiatric Association wishes to submit the following report. The committee feels that this report should be simply one pointing out to the Association certain important facts and situations that now exist in the field of social work in its relation to psychiatry. Therefore, no detailed information or statistical material on which this report is based, are given in this report.

The committee feels that the subjects discussed in this report are of such vital importance, and the decision that must soon be made by the psychiatric profession, are of such far reaching significance to the individual members of the Association and of society itself, that they should be studied carefully by the individual members and discussed in the meetings of the Association and its various sections. The committee also feels that definite authority should be vested in the committee, or in specially selected groups representing the executive committee to take official action from time to time in matters covered by this report.

* Deceased.

The committee would first call attention to the very remarkable growth of social work as a profession. This growth is manifest both by an increased number of schools and universities offering courses in social work and by the number of social workers now working who have received some form of training. This number has increased greatly in the past five years. Most of these trained or partially trained workers have had some training, in name at least, in psychiatry and mental hygiene. Some of them have had excellent training. Many of the members of the social work group have advanced to important positions such as: heads of agencies, public officials, especially in the public relief and planning fields, university teachers, judges in juvenile courts, law makers, official advisers, and cabinet members. These people are bringing into these fields what is usually called, "the psychiatric or mental hygiene approach." In these fields there is a very insufficient representation of psychiatrists specially interested in broad social problems. Many individuals that are non-medically trained are being used as psychiatric consultants.

Another important change is this: Until recently in the social work field, there was more or less sharp demarcation between the psychiatric social worker and what was known as the social case worker. Social case work has developed, and is changing rapidly and profoundly, and this demarcation, both in the training and in the practice, is less distinct than it was and its tendency is to disappear altogether. In practice, all social workers are becoming psychiatric social workers. The extramural psychiatrist cannot be expected alone to solve these problems nor can the psychiatrist alone do this. It has become a matter of great importance to the entire medical group.

With the rapid growth of social work as a profession, and the great increase in the scope of its activities, and because of the almost universal feeling among social workers that personality adjustments and mental deviations as well as mental disease, are an inseparable part of the problems the social worker must deal with after he meets the individual or the group, social workers feel that the psychiatric profession has, in a large measure, failed to keep pace with them in supplying the help they need. It is a recognized fact by all familiar with this field that were the number of psychiatrists now engaged in extramural and social psychiatry multiplied by one hundred, the psychiatrists themselves could not carry on the therapy, both simple and complex, in the fields that social work has already opened. Social work needs from the psychiatric profession the following things:

1. Help in setting up and maintaining standards of training for social workers, and supervision of students in training; mental hospitals as field training resources where a high calibre of social work is available for supervision.

2. Psychiatrists to teach mental hygiene and allied subjects in the schools of social work, and psychiatrists trained to give the type of consultation and treatment supervision the social worker needs and is being trained to use.

3. Social work needs from the general medical profession an increased interest in, and ability to help, the social worker with the problems of early mental disease, neurosis and personality deviations. Your committee feels that this is a very important need.

4. A clear and more generally accepted definition of the relation of the psychiatrist to the social worker, especially in the social workers' psychotherapeutic activities.

Psychiatry is now confronted with a very similar situation to that of the general medical profession 25 years ago when public health and personal hygiene representing the socialization of medical science first came to the notice of the entire country. Then, as now, the need for public health programs crystallized this issue. The history of what happened then is well known to the members of this Association. The question that confronts psychiatrists is, "Do we want to maintain the leadership and direction in the great and rapidly increasing field of mental hygiene?" If we do not accept this larger responsibility, a new profession will develop. It is not the social worker who is unwilling to wait for us to decide, but rather the public at large.

We are today confronted with a new set of conditions that force the psychiatrist to face this issue and to decide either to extend his help in the direction of social and community issues or to remain cloistered in older confines. The enactment of a number of laws encouraging the extension of material elements, buildings and equipment—encourage his sequestration; the enactment of other laws having to do with the security of people, especially the Social Security Act, opens the door for him. The administration of this Act, which is a functional provision, will demand many decisions as to the extent of psychiatric service, standards of such service in communities and possibilities of consultation. These require of the psychiatrist more than a willingness to cooperate; they require that he orient himself in social psychiatry and even more in the functions and processes of the various agencies with which he will cooperate. These federal laws and their local counterparts should be studied carefully by members of this Association and preparation made to meet their implications. It is to take care of requests for advice from official authorities in this situation that this committee strongly recommends to this Association: (1) that a committee with authority to speak for the Association shall be created as advisers available to act officially in such matters; (2) through giving all its support to the development of satisfactory standards of social work and the opportunity for the training of social workers, its members take the lead in the establishment of an effectual and standardized curriculum of psychiatric social work training; (3) for this purpose the committee shall actively participate in any joint effort, *e. g.*, by the establishing of a joint committee with the American Association of Schools of social work, to set up such standards of training and provide opportunity for field training in institutions and clinics under the control of the members of this Association.

At the present juncture it is probable that many members of the Association will be consulted individually and collectively with regard to community psychiatric activities. This committee will be glad to advise such members so consulted when the members feel they would find such advice useful. It believes it will be well to have this fact brought to the attention of the

general membership by means of an editorial in the JOURNAL of The American Psychiatric Association.

SAMUEL W. HARTWILL, M. D., *Chairman*,
EARLE W. FULLER, M. D.,
MESROP A. TARUMIANZ, M. D.,
GEORGE S. STEVENSON, M. D.,
HENRY I. KLOPP, M. D.

REPORT OF THE CHAIRMAN OF THE COMMITTEE ON RESEARCH.

There has been no formal meeting of the committee during the current year, but the chairman has been in correspondence with individual members. One of the members (Dr. L. E. Hinsie) has considered the responsibilities of the Committee on Research, and suggests the following: (1) "to act as advisers on anticipated research problems"; (2) "to suggest topics for research"; (3) "to read manuscripts critically"; (4) "to indicate what funds or endowments might be available." These topics are discussed in detail in his letter which is appended to this report.

A former member of the committee (Dr. Gregory Zilboorg) has offered a fruitful suggestion: "of developing, through the research committee, a focus of interest in the history and development of psychiatric concepts." The chairman has long felt the lack of a convenient source of such information; moreover, such a center of interest would be useful to the younger psychiatrists in particular, many of whom fail to realize how much we owe to our antekraepelinian predecessors, and conversely, how far we have come in what will soon be a century of organized American psychiatry. It is perhaps not too soon to be looking forward to a survey of the latter aspect of the subject for the centenary (1944) of the Association.

The chairman has completed a list of articles published by Fellows and Members and indexed in Vols. 17, 18 and 19 of the "Quarterly Cumulative Index Medicus." He has grouped the members geographically in regions of approximately the same membership, so as to compare the relative "literary" output; also affiliation or non-affiliation with hospitals has been taken into account. The original articles have been classified under 15 general heads. This material, and in addition population statistics, has been embodied in a table which is attached as a supplement to this report. This table has been of interest, and possibly of some use, to the Mental Hospital Survey Committee, with whose work our Association is cooperating.

The chairman wishes to call attention to the work of a member of the committee (Dr. Walter L. Bruetsch) who has continued to devote a great deal of time and attention to organizing the annual scientific exhibits, as well as presenting a large amount of pathological material of his own. The chairman would also like to signalize the book recently published by Dr. Nolan D. C. Lewis (in connection with projects subsidized by the Scottish Rite Masons of the Northern Jurisdiction) on "Research in Dementia Præcox." This book will answer many questions which might otherwise be addressed

to the committee. It would be desirable if such a study could be extended to the whole field of psychiatry.

Finally, there is a good chance that the National Research Council, through one or more of its committees, may, in the near future, take a more direct interest in promoting experimental research into the etiology of abnormal behavior reactions. The chairman, who is ex-officio a member of the Medical Division of National Research Council, is not in a position to give any further details at this time. In other respects the National Research Council is continuing lines of research outlined in previous reports.

Respectfully submitted,
CLIFFORD B. FARR, M. D., *Chairman*,
JOHN C. WHITEHORN, M. D.,
E. L. HORGER, M. D.,
WALTER L. BRUETSCH, M. D.,
LELAND E. HINSIE, M. D.

REPORT OF THE COMMITTEE ON RESOLUTIONS.

The Committee on Resolutions presents the following report:

We wish first of all to express our best appreciation to the Committee on Arrangements, under the able chairmanship of Dr. Frederick, for the admirable manner in which it planned for the pleasure and profit of those attending this convention, the success of which has been so largely due to its efforts, and to the Ladies Committee which so ably assisted it.

To the President, Dr. Campbell, to the Secretary, Dr. Sandy, to the Council and to the Committees we have only praise for the very efficient manner in which they have performed their duties. The Presidential address of Dr. Campbell leaves us permanently indebted to him. We are also grateful to the Guest of Honor at the Annual Banquet, Dr. John Gabbert Bowman, Chancellor of the University of Pittsburgh, for his remarkably inspiring address.

To all those who contributed papers at the various sessions we owe a real debt of gratitude. The papers were uniformly of high excellence, reflecting keen scientific knowledge, interest, energy and ability, and we have all benefited from these presentations. The arduous task of preparing the program for the various sessions and sections has been ably performed by the Committee on Program. We feel this Committee is to be commended for the excellence of its work and our particular congratulations are extended to its very efficient chairman, Dr. Roscoe W. Hall.

The thanks of the Association are also extended to Dr. Walter Bruetsch for his splendid arrangement of the scientific exhibits, and to those who prepared such exhibits and motion picture presentations for the edification of the convention. The commercial exhibitors are, of course, also included in this appreciation.

The press is to be particularly commended for the restrained yet thorough manner in which it has disseminated for the benefit of the public, those matters of great scientific and public interest which have been discussed in our meet-

ings and in which it has been ably assisted by the Committee on Public Education under the capable chairmanship of Dr. C. C. Burlingame.

To the hotel management and Convention Bureau for their fine cooperation, to Miss Crowe, our official reporter, for her excellent work, to the Kaufmann Company, the Heinz Company, the St. Francis Hospital for their entertainment, and to all others who have had any part in helping to make this convention so thoroughly successful, we extend the grateful thanks of the Association.

GEORGE H. STEVENSON, M. D., *Chairman,*
FRANK E. LESLIE, M. D.,
TITUS H. HARRIS, M. D.

Comment.

GOVERNMENTAL POLICIES IN NEW YORK AND MASSACHUSETTS.

It is an arresting coincidence and an enlightening illustration of opposite governmental policies in the administration of state mental hospital services that within a twelvemonth appointments to the headship of these services should have been made in two great States which had hitherto gone hand in hand in the van of every advance movement in dealing with the vital social problem of the care of the mentally ill.

The march to the rear of former Governor Curley of Massachusetts has been dealt with in previous editorial comments in the JOURNAL. By the displacement of Dr. Winfred Overholser as commissioner of the Department of Mental Diseases, Massachusetts lost the services of one of its most valuable officers. It is gratifying to note that the federal government has been quick to take advantage of the situation by appointing Dr. Overholser to the superintendency of St. Elizabeths Hospital in Washington.

Hard upon the unfortunate happenings in Massachusetts comes the retirement of Dr. Frederick W. Parsons, commissioner of the Department of Mental Hygiene of the State of New York, but with what contrast of circumstance. Governor Lehman expressed his great regret that in respecting the wishes of Dr. Parsons he must accept his resignation. In his letter to the commissioner he paid high tribute to his splendid service of thirty-five years.

> During this long period you have served the state with unusual fidelity, devotion and efficiency. On behalf of the people of the State may I thank you very heartily for your splendid service.
>
> I want you to know that my association with you, both as Lieutenant-Governor and Governor, has been a most happy one and that I shall very greatly miss your loyal assistance and wise counsel.

In such manner the Governor of New York expressed appreciation of the work of a faithful servant.

At the same time in the appointment of the new commissioner, Dr. William J. Tiffany, Governor Lehman voiced his satisfaction that he was able to promote a trained and trusted official who had come up from the ranks, one who has had long experience in all phases of clinical and administrative psychiatry and who enjoys in such large measure the respect and confidence of his colleagues. Under Dr. Tiffany's guidance the department built up by Dr. Parsons may be expected to flourish.

Massachusetts and New York—the contrast is exemplified in the two comments which follow.

DR. OVERHOLSER BECOMES SUPERINTENDENT OF ST. ELIZABETH'S HOSPITAL.

The appointment by President Roosevelt of Dr. Winfred Overholser, of Wellesley, Massachusetts, as superintendent of St. Elizabeth's Hospital to fill the vacancy caused by the death of Dr. William A. White is gratifying to psychiatrists who are familiar with the situation. Dr. Overholser assumed the duties of his new post on October 4, 1937.

On December 4, 1936, Dr. Overholser, after 17 years of outstanding service to the state hospitals in Massachusetts, was replaced as Commissioner of the Department of Mental Diseases by the then Governor of Massachusetts. This political stroke was followed by a succession of blows to the Department of Mental Diseases and the state hospitals of Massachusetts and the loss of Dr. Overholser has been felt keenly in his native state. This loss by the Commonwealth of Massachusetts has been converted into a gain for St. Elizabeth's Hospital by rendering available a man of this caliber to succeed the late William A. White, who won recognition as dean of hospital psychiatry in America.

Dr. Overholser's training and teaching experience as professor of psychiatry at Boston University, School of Medicine, and lecturer, Boston University, School of Law, preeminently qualify him for the teaching assignments which are associated with the appointment. Dr. Overholser is a recognized authority on forensic psychiatry and his publications are widely known to psychiatrists and to all who are interested in medical jurisprudence.

He was born in Worcester, Massachusetts, April 21, 1892; was educated in the public schools of Wellesley, Massachusetts; received his A. B. degree, *cum laude,* from Harvard College in 1912, and his M. D. degree from Boston University, School of Medicine, in 1916. After a residency of one year at the Evans Memorial Hospital in Boston, he entered the state service as assistant physician at Westborough State Hospital in 1917. His professional career was devoted to the state hospitals of Massachusetts except for a period of one year, 1918-1919, when he was a lieutenant, Neuropsychiatric Section of the U. S. Army Medical Corps and served overseas.

His progressive and consistent promotions from assistant physician to Commissioner of the Department of Mental Diseases, with a succession of experiences in clinical and administrative psychiatry, presaged the high honor which has been accorded him by the St. Elizabeth's appointment.

Dr. Overholser was president of the Massachusetts Psychiatric Society, 1933-1934, and president of the New England Society of Psychiatry, 1936-1937; is councillor and member of the Executive Committee of The American Psychiatric Association; member of the Executive Committee of the Cooperative Committee for the National Survey of Public Mental Hospitals Services in the United States; member of the Committee on Post-Graduate Instruction of the Massachusetts Medical Society; chairman of the Committee on Legal Aspects of Psychiatry of The American Psychiatric Association; member of the Committee on Psychiatric Jurisprudence of the American Medical Association; member of the Committee on Scientific Administration of the National Committee for Mental Hygiene, and consultant in psychiatry in the U. S. Public Health Service. He was formerly consultant in the medical aspects of crime of the National Crime Commission; secretary of the Massachusetts Chapter of the American Institute of Criminal Law and Criminology; member of the Executive Committee of the Massachusetts State Conference of Social Work; chairman of the Committee on Delinquency and Prisons, First International Conference on Mental Hygiene; Chairman of the Hospitalization Committee of the Department of Massachusetts of the American Legion. Recently, he has been actively engaged in surveying mental hos-

pitals in the United States and Canada as director of the National Hospital Research Division of the National Committee for Mental Hygiene.

Always interested in medical progress and research, Dr. Overholser's unique training and experience, together with his stimulating and sympathetic personality, offer St. Elizabeth's Hospital fortunate compensation for its recent loss. Dr. Overholser's popularity in medical organizations and in fraternal circles has parallelled his leadership in his chosen field. He was married June 4, 1919, to Dorothy Stebbins of Worcester, Massachusetts; they have three children, Dorothy, Jane, and Winfred, Jr.

RETIREMENT OF COMMISSIONER FREDERICK W. PARSONS AND APPOINTMENT OF DR. WILLIAM J. TIFFANY.

Dr. Frederick W. Parsons, Commissioner of the Department of Mental Hygiene of New York State since January 1927, retires from the Department on October 1. In Dr. Parsons' place Governor Lehman has appointed Dr. William J. Tiffany, superintendent of the Pilgrim State Hospital.

Dr. Parsons entered the New York State Hospital Service in 1902 when he was appointed to the staff of the Hudson River State Hospital, Poughkeepsie, New York. While there he reached the grade of first assistant physician in which position he served for six years until he enlisted in the Medical Corps of the United States Army in June 1917. He was first assigned to the British Forces, studying cases of war neuroses under Sir Frederick W. Mott of London. After the United States entered the war, he was transferred to the American Forces and became commanding officer of Base Hospital No. 117 where he served with efficiency and distinction and achieved the rank of lieutenant-colonel. Following his discharge from the Army, Dr. Parsons acted for a short time as medical inspector of the State Hospital Commission, and in April 1919 was appointed superintendent of the Buffalo State Hospital. On July 1, 1926, he was appointed by Governor Smith member and chairman of the New York State Hospital Commission to succeed Dr. C. Floyd Haviland. When in January 1927

the reorganization of the State Departments became effective and the former State Hospital Commission became the Department of Mental Hygiene, Dr. Parsons was appointed by Governor Smith as Commissioner of the Department. Because of the provision in the amended State Constitution that heads of departments were to be appointed by the Governor and their terms were to be coterminous with his own, there was considerable doubt in the minds of some persons as to whether such an arrangement with its potential uncertainty of tenure of office would be best for the operation, particularly of the Department of Mental Hygiene, and whether it would attract the best type of physician to head such a Department. The last ten years have dispelled doubts of this nature. Dr. Parsons has continued in office by reappointment by Governors Roosevelt and Lehman and the Department of Mental Hygiene has been recognized as one of the best organized and operated of the several State Departments.

The state has been fortunate in having governors with vision to recognize the ability of Dr. Parsons, and the state has likewise been fortunate in having a commissioner such as Dr. Parsons willing to serve as the head of a Department which has the responsibility of administration of twenty-six large institutions for the mentally ill and the mentally defective. During Dr. Parsons' administration an extensive building program has been carried out including the construction of several large new hospitals and additions to those already existing. At all times he received the wholehearted and deserved cooperation of the superintendents and Boards of Visitors of the state institutions. Dr. Parsons has not only been an able administrator but his sympathy for, and interest in, research was continuously demonstrated by his encouragement and support of the activities of the Psychiatric Institute and Hospital and by the more recent establishment of the treatment of dementia præcox by means of insulin in all the state hospitals. Psychiatry in this country can well be proud of having such an outstanding exponent of sound principles of hospital administration for the care of the mentally ill.

New York State continues to be fortunate in having as Dr. Parsons' successor Dr. Tiffany, who has had an experience of over thirty years in the State hospital system of New York and

who during this time has evidenced such outstanding ability as to raise no question that the Department of Mental Hygiene will remain in good hands.

Dr. Tiffany began his service at the Binghamton State Hospital in 1904 and had associations there with Dr. William A. White, Dr. Charles G. Wagner and Dr. James V. May, all former presidents of The American Psychiatric Association. For a number of years Dr. Tiffany was pathologist at the Binghamton State Hospital and later held that position at the Manhattan State Hospital. He was appointed clinical director of the Kings Park State Hospital in 1922 and became superintendent there in 1926. When the new Pilgrim State Hospital, which was contemplated as the largest of its kind in the world, was under construction and organization, Dr. Tiffany was selected by Dr. Parsons as the one best suited to carry on the difficult tasks of that development, and Dr. Tiffany was appointed as superintendent of the Pilgrim State Hospital in 1931. He has shown during the past six years the ability to meet and solve problems that would be to many insurmountable. Through his natural qualifications and training Dr. Tiffany has an unusual combination of resources in fields of hospital construction and administration, treatment and research; and it may be safely anticipated that the New York State Department of Mental Hygiene under Dr. Tiffany will continue the progress that it has shown in the past ten years, and demonstrate anew the importance of having a man at its head who has reached his position because of training and experience and not through political expediency.

C. O. C.

News and Notes.

94TH ANNUAL MEETING.—The annual meeting of the Association will be held in San Francisco, June 6-10, 1938, with headquarters at the Fairmont Hotel. This meeting is especially noteworthy as it is the first time that the Association has gone to the Pacific coast to hold its annual session; and it is anticipated that this fact will bring a large attendance of members who will be glad to avail themselves of the opportunity of combining with the regular annual meeting a visit to San Francisco and the West.

To this end special all expense tours have been arranged, notices of which have been sent to members from the New York office by Mr. Austin M. Davies, executive assistant, to whom inquiries for further information may be addressed.

ANNUAL MEETING, AMERICAN MEDICAL ASSOCIATION.—The 1938 annual sessions of the American Medical Association will be held in San Francisco, June 13 to 17. These meetings follow directly upon The American Psychiatric Association save for the week-end interval.

Members who wish to attend the meetings of the American Medical Association are informed that if they wish an extension of their hotel accommodation it will be necessary to arrange for this with the Hotel and Housing Committee of the American Medical Association, Suite 2004, 450 Sutter St., San Francisco, California. Space in all hotels is being reserved by the Americal Medical Association beginning at noon June 10, 1938, which is the final day of The American Psychiatric Association meeting.

SCIENTIFIC EXHIBIT AT THE ANNUAL MEETING IN SAN FRANCISCO IN 1938.—There will be a scientific exhibit at the next annual meeting of The American Psychiatric Association. The following topics for the purpose of general orientation are suggested: interesting material relating to neuropathology, neuroanatomy,

new laboratory procedures, clinical psychiatry, mental hygiene, child guidance, diagnostic methods, statistical researches, etc.

Important aids toward a successful scientific exhibit are personal demonstration; plainly lettered posters; statement of purposes or justification of exhibit; and neatness and care in planning material. The scientific exhibit offers an opportunity for investigators and visiting members to meet and discuss informally the various phases of the research work presented. The exhibit is also of special advantage to persons reading papers since the exhibit can be used to supplement the papers read. Application for space with a short description of the exhibit material, not exceeding 150 words, should be submitted to the Director of the Scientific Exhibit, Dr. Walter L. Bruetsch, Central State Hospital, Indianapolis, Indiana, not later than March 1, 1938.

Medical Society of St. Elizabeth's Hospital (Washington, D. C.).—This Society was recently organized in Washington by a number of present and former members of the medical staff of St. Elizabeth's Hospital. It is planned as an alumni society of the hospital, to include physicians now serving, or having served in the past, on the hospital staff. In general, it will sponsor and support efforts to promote the best interests of the hospital and will serve to maintain among its members pleasant associations with the hospital and with each other. The encouragement of a program of guided psychiatric research at the hospital is a contemplated feature of the work of the Society.

Officers elected at the initial meeting are: Dr. Addison M. Duval, president; Dr. Joseph L. Gilbert, vice-president; Dr. Jay L. Hoffman, secretary.

Communications from former staff members (including medical officers in the military services who have been assigned to the hospital) are invited and should be addressed to the Secretary, Medical Society of St. Elizabeth's Hospital, St. Elizabeth's Hospital, Washington, D. C.

Fellowship Opportunities.—A limited number of fellowships have been provided by The Commonwealth Fund and other sources

for training in extramural psychiatry. These fellowships are to be administered by The National Committee for Mental Hygiene, through whom fellows are to be assigned for one or two years to a selected child guidance clinic, the term and plan of the fellowship to be determined by the peculiar needs of the fellows. Candidates for fellowship award should have had at least two years of psychiatry in an approved mental hospital service, in addition to other qualities fitting them for extramural work. This provision of training fellowships comes in response to a definite paucity of personnel in this field. Accordingly, other conditions as to age, sex, marital status, etc., must be governed by individual cases and by the nature of current demand. Requests for further information about these fellowships, and applications therefor, should be addressed to Dr. George S. Stevenson, The National Committee for Mental Hygiene, Room 822, 50 West 50th Street, New York, N. Y.

FELLOWSHIP APPOINTMENTS, 1937-1938.—Under a grant from The Commonwealth Fund, the National Committee for Mental Hygiene has made the following appointments for one year's training in extramural psychiatry:

At the Judge Baker Guidance Center, Boston, Dr. Reynold A. Jensen, a graduate of University of Minnesota Medical School, with one year each at the Psychiatric Department of Strong Memorial Hospital, Rochester, and the Pennsylvania Hospital in Philadelphia.

At the Louisville Mental Hygiene Clinic, Dr. Edward Everett Landis, who obtained his medical degree from Northwestern University and comes to this fellowship from the Fulton State Hospital in Missouri.

Dr. Joseph C. E. LaVallee to the Child Guidance Clinic in Cleveland. Dr. LaVallee obtained his medical education at Syracuse University in 1926 and has recently been resident psychiatrist at the Buffalo City Hospital.

Dr. Robert Penn Kemble to the Philadelphia Child Guidance Clinic. Dr. Kemble is a graduate of Jefferson Medical College, 1933, and served a residency at the Pennsylvania Hospital and the Payne Whitney Clinic, New York Hospital.

GRADUATE CLINIC AT RALEIGH, NORTH CAROLINA STATE HOSPITAL.—Dr. Julian W. Ashby, superintendent of State Hospital, Dix Hill, Raleigh, N. C., by arrangement with the New York State Psychiatric Institute, provided a two weeks graduate clinic at the Raleigh State Hospital, August 1-14, 1937.

This clinic was conducted by Dr. Joseph R. Blalock of the New York State Psychiatric Institute, and included some of the features of the two weeks graduate course given each autumn at the New York State Psychiatric Institute. The program consisted of lectures on the biogenetic psychoses, the psychoneuroses and psychosomatic relations; clinical conferences in which cases were presented by members of the staff; presentation by the staff of reviews of selected publications; and ward rounds in which special attention was given to the problem of insulin therapy and the treatment of neurosyphilis.

MISSISSIPPI VALLEY MEDICAL SOCIETY AWARD.—The Mississippi Valley Medical Society (Tri-State Post-Graduate Assembly of Illinois, Missouri, and Iowa), offers a cash prize of $100.00, a gold medal and a certificate of award for the best unpublished essay on a subject of interest and practical value to the general practitioner of medicine. Entrants must be ethical licensed physicians, residents of the United States and graduates of approved medical schools. The winner will be invited to present his contribution before the next annual meeting of the Mississippi Valley Medical Society (September 28, 29, 30, 1938), the Society reserving the exclusive right to first publish the essay in its official publication—the Radiologic Review and Mississippi Valley Medical Journal. All contributions shall not exceed 5000 words, be typewritten in English in manuscript form, submitted in five copies, and must be received not later than May 15, 1938. Further details may be secured from Harold Swanberg, M. D., Secretary, Mississippi Valley Medical Society, 209-224 W. C. U. Building, Quincy, Ill.

CIVIL SERVICE EXAMINATIONS.—The United States Civil Service Commission announces open competitive examinations for the following positions:

Junior medical officer (rotating interneship), $2000 a year.
Junior medical officer (psychiatric resident), $2000 a year.

The place of employment is to be St. Elizabeths Hospital, Washington, D. C. Applications for these positions must be on file with the U. S. Civil Service Commission, Washington, D. C., not later than November 29, 1937, if received from states east of Colorado, and December 2, 1937, if received from Colorado and states westward.

For the position of junior medical officer (rotating interneship) applicants must be fourth-year students in a grade A medical school. For the position of junior medical officer (psychiatric resident) applicants must have successfully completed four years of study in a grade A medical school not prior to January 1, 1935, and must have the degree of either B. M. or M. D. In addition they must have successfully completed an interneship of at least one year, provided that applications will be accepted from persons now serving an accredited rotating interneship.

Full information regarding these examinations may be obtained from the Secretary of the United States Civil Service Board of Examiners at the post office or customhouse in any city which has a post office of the first or second class, or from the United States Civil Service Commission, Washington, D. C.

Book Reviews.

PERSONALITY AND THE CULTURAL PATTERN. By *James S. Plant, M.D.* (New York: The Commonwealth Fund; London: Humphrey Milford, Oxford University Press, 1937.)

The central theme of this book is that the personality is in large measure the result of the cultural pattern in which the individual lives. The task of psychiatry and mental hygiene is thus not alone to deal with the individual but to concern itself also with alteration of the cultural pattern. In such alterations, human institutions must be evaluated in the light of what they mean to individual men, women, and children.

The author distrusts, possibly too much, mere statistical or questionnaire approaches to the study of the relationship of the individual and the social institution. One proposal which he makes for the better understanding of this relationship is what he terms the "casual breakdown." This term is used to describe a situation in which the individual finds himself in a short and dramatic dislocation with a given social institution. Thus the first overt truancy illuminates the question "What does school mean to me?" The slammed door of the husband, "never to return," appraises certain things that marriage has meant to that man. The author emphasizes the point that there are certain to be artifacts in material collected in connection with such dramatic incidents, but if a sufficient number of cases are collected, he believes the method will contribute much to an understanding of the individual-institution relationship.

From the standpoint so established, the author discusses the concepts of classical psychiatry and the structure of the personality in relation to environmental pressures. The part of the family, the school, recreation, law and order, social work, medicine, the church, and industry are all considered in this connection.

This book contains much information and many arresting suggestions. One who tries to read it, however, in an objective mood cannot help feeling that the author has possibly even too well integrated in its pages his own value judgments concerning present-day social institutions and his factual observations. For example, he says "The schools have been interested to know how large an amount of academic knowledge could be given to children. The really more pressing question is how little of it will permit the individual to live comfortably with others at his chosen level and will also meet the demands of the welfare of the group." Surely there are still valid arguments in favor of the older conception of education here dismissed. In the author's conclusions on this and other social questions, the reader may well

remember that the author's evaluations are based upon a certain philosophy of social psychiatry and that therefore another social philosophy might well lead to different and sometimes even opposed value judgments.

LEONARD CARMICHAEL, PH. D.,
University of Rochester.

MODERN DISCOVERIES IN MEDICAL PSYCHOLOGY. By *Clifford Allen, M. D., M. R. C. P., D. P. M.* (London and New York: Macmillan and Company, Ltd., 1937.)

The author of this book says that "it is hoped that it may interest the general practitioner, the medical student and even form an introduction for those who intend to read for the Examination for the Diploma of Psychological Medicine." As used in this book, the term *modern* is "taken to include the last 40 years," but it seems to the reviewer that the emphasis is given to the first rather than to the second 20 years of this period.

Unlike most scientific works this volume has a plot. It begins in a discussion of the work of Mesmer and his followers in hypnotism. It shows how, in the author's opinion, this point of view led to the positions of Janet, Morton Prince, and their associates. Thus the way was prepared for the "discovery of psychoanalysis" by Freud. This discovery was essentially that "the real cause of the patient's illness was locked away deep down in his unconscious mind. But more than this, *he* (Freud) *knew how to rescue the idea from the depths of oblivion.*" The discussion of Freud is eulogistic. The reader is told, "Now, it must be admitted that the enemies of Freud must be careful not to admit any single part of his discoveries to be valid, since one part is interlocked with the other part, and if one admits that one thing is correct, one is forced to admit the validity of the whole edifice. . . . . If one once admits that Anna, Freud's little daughter, dreamed of tasty food because she had had no food all day on account of a bilious attack—that she wished for tasty food, and this caused the dream, then one must admit that all dreams are due to wishes. At this stage one is gained as an adherent to Freud forever." Again, the reader is told that "There is one branch of psychological medicine which is the direct offshoot from Freud's work and which has not been touched on before, and that is child analysis and child guidance. It is on this that great emphasis has recently been laid. The most surprising thing in the world is the way in which young children will respond to a change of environment and a little assistance over their emotional difficulties. If only all children could be observed when they were in the process of forming a neurosis and treated at once, it would be safe to say that the incidence of this type of illness would be reduced enormously." One is tempted to ask if a change of environment and a little assistance over emotional difficulties necessarily constitute a direct offshoot from Freud's work.

Following the chapter on Freud, there are chapters giving clear pictures of the contributions made by Adler and Jung to medical psychology. Both of these chapters are, nevertheless, written from a distinctly Freudian point

of view. Then there follow in the book, surprisingly enough, chapters on Kretschmer and Pavlov. Kretschmer's type-theory is described in a rather favorable way. It is true, however, that without further explanation, the statement is made that "Kretschmer's work had been severely criticised in America, and we must be cautious in accepting it in an uncritical way."

The final chapter on Pavlov is an informative brief summary of the work of this investigator. The chapter does not, however, give any clear indication of the vast amount of work on conditioning done both in Russia and America by scientists other than Pavlov. Brief mention is made of behaviorism, "elaborated by John B. Watson in America," but no discussion is presented of the large amount of quantitative work which has grown out of, and which indeed in some measure preceded, Watson's objective experiments on emotional and other types of learning in children.

The first paragraphs of this book give faint praise indeed to academic psychology before turning to the "discoveries" of abnormal psychology. Unfortunately, however, the present volume gives very little consideration to the respectable body of fact accumulated by the academic experimental psychology of our day. It is true Dr. Allen cites C. L. Hull's book, *Hypnosis and Suggestibility: An Experimental Approach,* but he gives the author's name a wrong initial and certainly in no way suggests interest in the quantitative facts which have come out of laboratories of experimental psychology concerning the phenomena of hypnosis and which are summarized in Hull's book.

Dr. Allen unfavorably criticizes the wordiness of academic psychology, but in his own work, he employs such words as "mind," "consciousness," "psychical energy," "the unconscious," and the like without making clear the definitions which he accepts.

In the last chapter, the author expresses himself as sympathetic to an approach toward an understanding of mental processes by the study of the behavior of the human organism and the physiology of the nervous system. Here is a rigid determinism to contrast with the essential vitalism of the libido theories discussed in much of the book. In spite of this possible fundamental difference, Dr. Allen says "Pavlov's work does tend to throw a great deal of light on the work of Freud, and their theories are not really mutually incompatible. . . . . We cannot help agreeing that his work is even more fundamental than Freud's, and that eventually it may lead to something of great value." With this point of view, the reviewer finds himself in complete accord. Almost 30 years ago, E. B. Holt began the process of showing how certain of Freud's undoubted insights could be synthesized into a modern physiological psychology of behavior. The large literature which has developed out of this standpoint and the experiments upon which this point of view is based are not discussed in the present work. To compare the latter with such a volume as L. S. Shaffer's recent *Psychology of Adjustment* is to make this point clear.

Freudian psychoanalysis is well reviewed in this book, but, save for this material, it can scarcely be said to deal with modern psychology, at least

as the term is understood in America today. The "discoveries," moreover, which are emphasized in the book, such as that of "the unconscious," are not discoveries as that word is used in physical science. The concept of the unconscious still remains a theory, and one is tempted to remember the phrase of one of America's well known psychologists who suggested that at best, a theory is an individual's more or less blundering effort to organize the facts of observation. In the case of medical psychology, the data of observation are the objective facts of what human beings do and say and the demonstrated neural and physiological basis of such actions. From this point of view, a discussion of modern discoveries in medical psychology involves summarizing the recent advances in half a dozen medical sciences, not a mere re-telling of the story of psychoanalysis.

LEONARD CARMICHAEL, PH. D.,
University of Rochester.

AN INTRODUCTION TO ABNORMAL PSYCHOLOGY. Revised Edition. By *V. E. Fisher*. (New York: The Macmillan Company, 1937.)

This is the second edition of a textbook of abnormal psychology intended for college undergraduates who have had one previous course in general psychology.

The chapter headings give some idea of the scope of the book: 1. Abnormal Psychology; 2. The Normal Personality; 3. Personality Variants and Their Measurement; 4. Criteria of Personality Adjustment; 5, 6, 7, 8. Common Modes of Reaction to Difficulties; 9, 10, 11, 12, 13. The Psychoneuroses; 14. Some Borderline Conditions; 15, 16, 17. The Functional Psychoses; 18. Some Organic Psychoses; 19. Sleeping; 20. Dreaming; 21. Hypnotism and Suggestion; 22. The Feebleminded Individual; 23. A Word on Mental Hygiene.

A number of cases are cited in the book which well serve to illustrate the subject matter of the respective chapters.

The general standpoint from which this book is written raises a fundamental question as to the relationship between abnormal psychology and psychiatry. The reviewer tends to think of general psychology and abnormal psychology in their relation to medicine as strictly pre-clinical. If this distinction is a valid one, this book is both psychology and psychiatry. A combination work of this sort may well be of less value to those who expect later, as medical students, to have adequate instruction in psychiatry than would be a more strictly psychological book. It may well be, however, that a combination treatment of this sort may prove very useful to the future nurses, teachers, ministers, social workers, lawyers, and citizens who happen to study "abnormal psychology" in an undergraduate college and who never expect to receive any other systematic instruction in the abnormalities of mental life.

University of Rochester.

SUBSTITUTE PARENTS: A STUDY OF FOSTER FAMILIES. By *Mary Buell Sayles.* (New York: The Commonwealth Fund, 1936.)

A book dealing with the constructive aspects of foster family problems comes as a welcome contrast to the many reports in the literature which stress the unfavorable influences resulting from this relationship. In the present short volume, written for the general reader, the author gives an intimate picture of successful foster homes which were drawn into the service of child placement agencies.

The first part of the book, consisting of 70 pages, presents a concise general discussion of the problems inherent in foster family relationships, the motives which lead people to seek the experience of foster parenthood, and the information concerning both child and prospective home which is a necessary prerequisite to adoption. The author discusses both the constructive and destructive forces which must be reckoned with by women and men who essay to play the rôle of substitute parents. The material in these introductory chapters is presented in a practical, matter-of-fact way, reflecting the experience of the trained social worker who understands foster children and their setting from the standpoint of mental hygiene.

The second and larger portion of the book, 133 pages, contains eight chapters, each a detailed case study of individual children and their foster parents. These reports are written in an informal, narrative form, giving a factual sociologic account of the vicissitudes of child placement, the constantly changing developments, and the indispensability of follow-up supervision. In all instances there were more than the usual number of handicapping factors, yet through the selection of wise and capable foster parents each case was carried well on the way to a successful solution.

This work can be recommended as a helpful sociologic report of the constructive and encouraging aspects of guided foster family relationships, and is one that can safely be placed in the hands of intelligent adults who are desirous of adopting a child.

STUDIEN ÜBER DIE ENTWICKLUNG DER INTELLIGENZ BEI FRÜHGEBORENEN KINDERN. By *Torild Brander.* (Helsingfors: Akademische Buchandlung. Berlin: R. Friedländer and Sohn, 1936.)

The present book is in line with the recent tendency for a reorientation in the field of psychiatry and neurology, a tendency which emphasizes the importance of the study of the prenatal influences. In this volume only one problem is considered, namely, the relationship between premature birth and the development of intelligence. The study was carried out under the auspices of the Pippingskold Research Fund and the Finnish Scientific Society. In an introductory chapter Brander discusses the concept of premature birth from the obstetrical and pediatric standpoints. He considers the weight of 2,500 grams or less as a criterion for premature birth. He gives an interest-

ing historical review of the subject; it seems that Shakespeare was the first to point out in a monologue of King Richard III, the relationship between intracranial involvement and premature birth. King Richard III was prematurely born and Shakespeare's description of his physical condition would suggest the possibility of Little's disease. Of more scientific importance is the first communication on this subject made by Ritter in 1849, in which he reported a case of a 16 year old idiot born during the sixth month of pregnancy. Later, in 1862, the English orthopedist Little drew attention to this relationship. During the following years considerable disagreement prevailed among the various investigators, which Brander ascribes to such factors as heterogeneous nature of the material, failure to utilize the material to the fullest extent, difficulty in gauging the degree of intelligence defect at an early age and lack of uniform working criteria.

In order to obtain a clearer idea as to what happens to the prematurely born children Brander went over the records of the obstetrical hospital in Helsingfors from 1919 to 1927 inclusive. He found that there were 2310 premature births in a total of 18,073 births. The prematurely born children weighed from 600 to 2500 grams. Of these 1240 died at birth or shortly afterwards, while 1070 were sent home. Five hundred and eighty-three were still living when Brander undertook his investigation. Most of these children were between 7 and 15 years of age at that time. Brander examined 365 children personally; 153 children who were living in the provinces were seen by the local physicians; the rest failed to appear for examination. The Binet-Simon-Terman test was used. Most of the children attended the public school at that time. Because of the size of the group and the systematic methods used it may not be amiss to present here some of the findings obtained by Brander. He found that the later the children learned to walk the lower were their average and the high I. Q. values. He established a similar relationship in regard to speech. He also found that the average, the high and the low I. Q. values increased *pari passu* with the child's progress in school. The same was also true of children in high school. Of the entire group, 46 per cent of the children showed normal intelligence rating, 1.4 per cent were of the borderline type, while the remaining 52.7 per cent had a low intelligence level. Of the entire group 11.2 per cent belonged to the imbecile group. Brander claims to have found a distinct relationship between the I. Q. and the weight of the child at birth; children weighing below 1500 grams at birth constituted the low intelligence group, while normal intelligence ratings were found in children with weight at birth of 1510 grams and more, and finally high intelligence was observed in children with 2110 grams and more. With the help of a standard curve Brander attempted to show that the relationship between the weight deficit and intelligence unit amounts to 500 grams for every seven or eight I. Q. units.

Of the other facts, which, according to Brander, seem to have an unfavorable influence on the intelligence are psychic hereditary taints. However, he found among 42 instances of mental defect only 3 cases in which the hereditary element played a predominant factor. Epilepsy and various psychoses, except of luetic origin, in the ascendency played even a smaller rôle. On the

other hand, he found a definite relationship between alcoholic heredity and mental defect in prematurely born children. The triad of premature birth, delivery complications and psychic heredity has proven to be the most unfavorable combination with an incidence of mental defect in 35 per cent of the cases. In the absence of hereditary factors the percentage of mental defect in cases with birth complication in prematurely born children is higher than in uncomplicated deliveries. He believes that the danger is particularly great in cases with face presentation, in breech presentation, in precipitated delivery and delivery with high forceps and in extraction in breech presentation. He thinks that in eclampsia, in prolapse of small parts and in asphyxia the mental development will depend upon the immediate therapeutic intervention.

In another chapter he discusses the problem of twins. Here he pays attention to the mechanical element and to the fact that twins are frequently prematurely born. Children, out of wedlock, born prematurely are, according to the author, of a lower intelligence level as compared with legitimate offsprings. Brander thinks that this may be due in part to the lower social standing of the progenitors. He noticed that primogene children of older primparæ compare unfavorably with children born later.

Calculating that 12.8 per cent of all births during the period from 1919 to 1927 which took place in the maternity wards of Helsingfors University Hospital were premature, and that 25.2 to 35.9 per cent of these children survived to reach the school age, he therefore concludes that 3.2 to 4.6 per cent of the children in public schools of Helsingfors were prematurely born. Reasoning further that since 11.2 per cent of this group are mentally deficient, ½ per cent of all the children are therefore probably mentally defective because of premature birth. He further states that there is probably a direct relationship to premature birth in 12.5 to 25 per cent of all hypophrenias. He found relatively few cases with endogenous hereditary factors, such as mongoloid idiocy, myxedema or epilepsy and this brings him to the conclusion that the exogenous type of mental defect among prematurely born infants constitutes the majority. The practical conclusion which Brander draws from this investigation is that a more careful obstetrical prophylaxis must be carried out for the prevention of the exogenous type of mental deficiency.

This study may be a beginning in the right direction. Similar investigations may throw light on some of the still baffling psychiatric and neurologic problems.

The book is abundantly documented with charts, tables and case records.

Poughkeepsie.

NEW LIGHT ON DELINQUENCY AND ITS TREATMENT. Results of a research conducted for the Institute of Human Relations, Yale University. By *William Healey, M. D., and Augusta F. Bronner, Ph. D.* (New Haven: Yale University Press, 1936.)

This book is the result of a three year study in three different cities of 153 delinquents belonging to 133 families. Five hundred seventy-four mem-

bers of the families were examined and 145 non-delinquents were studied, 105 of them being utilized as controls. It is pointed out by the authors that the research was originally planned for ten years and that the number of patients studied was too small to make statistical conclusions of much value. There is, however, a fair amount of statistics in the book, aiding somewhat in understanding the work done, although much of the statistics adds nothing new to the subject, as the authors themselves have stated.

To the reviewer, there are some parts of the book which are extremely valuable and which should be emphasized. The first chapter on the significance of delinquency is an excellent summary of the subject. It is the type of thing that one wishes particularly that judges and all those having to do with delinquency, and who have not had thorough psychiatric training, should read. The question as to why some people refrain from delinquency as being a problem to be studied, the observation that in the delinquent cases "there had been no strong emotional tie-up to anyone who presented a pattern of satisfactory social behavior," the statement that "conscience may cover only certain areas in the field of conduct," all these are ideas which should be more generally diffused.

The attempt to use controls by studying non-delinquents in the same family appears to be an excellent way to approach the problem, and the study of twins is obviously one of the most ideal ways of getting such controls. The book then continues the study of these cases in an endeavor to determine what the delinquency represents to the individual, and on this basis treatment is outlined, with an endeavor to evaluate such treatment. The last chapter, "Practical Implications of the Research," sums up certain conclusions and opinions of the authors.

The book should certainly be read by all those interested in the problem of delinquency and its treatment.

KARL M. BOWMAN, M. D.,
New York.

THE NEUROTIC PERSONALITY OF OUR TIME. By *Karen Horney, M.D.* (New York: W. W. Norton & Co., Inc., 1937.)

This book is a refreshing rebellion against the orthodox Freudian doctrine in that it extends the etiology of the neuroses into other domains than the sexual phases of infancy and childhood. Most importantly, so far as the non-Freudian is concerned, it is a recognition on the part of those who do psychoanalysis of the social-cultural environment as a factor in the production of the neuroses, a discovery which the average practicing physician and the non-Freudian psychiatrist has taken for granted since Beard's day. This book is a belated discovery of America by a somewhat tardy Columbus.

The importance of the past, of the experiences of infancy and even of the fœtal state has been given exaggerated value by Freud and his followers. Dr. Horney seeks to bring the present, the adult life, into etiological relationship to the neuroses. She states:

"I do not consider it justified to focus our attention on childhood in a sort of one-sided fascination and to consider later reactions essentially as repetitions of earlier ones. I want to show that the relation between childhood experiences and later conflicts is much more intricate than is assumed by those psychoanalysts who proclaim a simple cause and effect relationship. Though experiences in childhood provide determining conditions for neuroses they are nevertheless not the only cause of later difficulties."

The author has evidently been greatly influenced by those anthropological writings which show that cultures differ widely, and that consequently the conduct of individuals in the various cultures has different norms. This, of course, is a classical attitude of psychiatry. It has long been known that the delusion, for example, is to be evaluated in accordance with the culture of the individual himself. As an illustration, if a Louisiana negro believes in Voodoo and governs his life accordingly, he is acting normally; whereas if a college professor were suddenly to embrace such a belief and to act in harmony, a psychosis would be reasonably suspected. The novelty of the book resides in the fact that a psychoanalyst has at last given weight and value to cultural factors.

Since the author regards anxiety as the central feature of the symptom-complex of the neuroses, she seeks to discover the difference between the neurotic and the non-neurotic so far as anxiety is concerned. Thus:

"The neurotic, however, not only shares the fears common to all individuals in a culture, but because of the conditions in his individual life—which, however, are interwoven with general conditions—he also has fears which in quantity or quality deviate from those of the cultural pattern."

She then makes another differentiation between the normal and the neurotic which is of interest (and arouses in the reviewer his skepticism):

"The normal person is capable of making the best of the possibilities given in his culture. Expressing it negatively, he does not suffer more than is unavoidable in his culture. The neurotic person, on the other hand, suffers invariably more than the average person. In fact, the neurotic is invariably a suffering person."

In a later stage she goes on to say:

"The neurotic himself may not even be aware of the fact that he is suffering."

The neurotic is described throughout the book as an individual incapable of feeling affection, although he desires love, and has "affect hunger" in a pathological sense. There is thus a long section which gives the various methods by which affection is secured. Securing affection in any form may serve as a powerful protection against anxiety, and the author pays especial attention to the varying techniques by which security is reached. Submissiveness becomes a way of satisfying anxiety and the desire for affection. The neurotic may attempt to reach power so as to secure himself against being hurt, the formula being, "If I have power, no one can hurt me." The final step for reaching security is withdrawal, which in addition to the meaning usually given this term also signifies the piling up of possessions, acquir-

ing affluence, becoming independent of others by one device or another, and so forth.

We are necessarily greatly interested, of course, in the author's definition of what is normal and what is neurotic. I cite an interesting paragraph. The neurotic and the normal are differentiated by Dr. Horney as follows:

"There are two characteristics, however, which one may discern in all neuroses without having an intimate knowledge of the personality structure: a certain rigidity in reaction and a discrepancy between potentialities and accomplishments.

"Both characteristics need further explanation. By rigidity in reactions I mean a lack of that flexibility which enables us to react differently to different situations. The normal person, for instance, is suspicious where he senses or sees reasons for being so; a neurotic person may be suspicious, regardless of the situation, all the time, whether he is aware of his state or not. A normal person is able to discriminate between compliments meant sincerely and those of an insincere nature; the neurotic person does not differentiate between the two or may discount them altogether, under all conditions. A normal person will be spiteful if he feels an unwarranted imposition; a neurotic may react with spite to any insinuation, even if he realizes that it is in his own interest. A normal person may be undecided, at times, in a matter important and difficult to decide; a neurotic may be undecided at all times."

Neither in Heaven nor on earth is there a normal person such as is implied in this paragraph. What is meant here is perfection in adjustment, not normality. The author continually shifts her definition of normality and neurosis to suit the situation. In fact, she takes the dangerous position that a person may have a neurosis without any symptoms whatever, and the diagnosis may be made by his personality or character pattern independently of any symptoms, thus following Alexander. As implied before, she states that the neurotic may not even be conscious of any difficulty or of any suffering, and in one place this statment is made concerning anxiety:

"Finally there are neurotic persons who are aware only of having depressions, feelings of inadequacy, disturbances in sex life, and the like, but they are entirely unaware of ever having or having had anxiety. Closer investigation, however, usually proves their first statement to be inaccurate. In analyzing these persons one invariably finds just as much anxiety beneath the surface as in the first group, if not more. The analysis makes these neurotic persons conscious of their previous anxiety and they may recall anxiety dreams or situations in which they felt apprehensive. Yet the extent of anxiety acknowledged by them usually does not surpass the normal. This suggests that we may have anxiety without knowing it."

The unregenerate may here whisper that very likely the patients have had no anxiety until the analysis brought it about. It is not unheard of in therapeutics that the cure brings about more damage than the disease.

The book goes on to deal at length with the various relationships between anxiety and hostility, the nature of sexuality, masochism, etc. We then run

into the "compensation by upside down," which is so flexible and bewildering a part of psychoanalysis. Thus, a domineering attitude is an expression of inferiority and anxiety, and a submissive attitude is likewise an expression of the same thing, although it may be an expression of superiority. Thus, retreat from woman and impotence may be the expression of a fear of woman, and an aggressive Don Juan career may have exactly the same significance. Love may basically express hate, and hate is the expression of a love that is concealed. This is the most convenient device of thought which ever appeared on the human scene.

Finally, after a long account of the neuroses, which space forbids me to analyze, we come to the last chapter which is called "Culture and Neurosis." In this chapter the author attacks the typical Freudian position, to wit:

"That wars are caused by the working of the death instinct, that our present economic system is rooted in anal-erotic drives, that the reason the machine age did not start two thousand years ago is to be found in the narcissism of that period."

While accepting the main theses of the Freudian doctrine, she states:

"The error consists primarily in assuming a quantitative instead of a qualitative relation. The relation is not between quantity of suppression and quantity of culture but between quality of individual conflicts and quality of cultural difficulties. The quantitative factor cannot be disregarded, but it can be evaluated only in the context of the entire structure."

With this very profound and somewhat unintelligible statement, she comes down to the typical difficulties inherent in our culture which mirror themselves as conflicts in every individual's life and which, accumulated, may lead to the formation of neuroses. These factors are—modern culture is economically based on the principle of individual competition. . . . . The psychic result of this situation is a diffuse hostile tension between individuals. . . . . This competitiveness and hostile tension pervades the entire life including the familial, economic, sexual—all relations of the human being are invaded by this factor. Consequently, there is a constant generation of fear. Therefore, this results psychologically in the individual feeling that he is isolated. Even when he has many contacts with others, even when he is happily married, he is emotionally isolated. Emotional isolation is hard for anyone to endure; it becomes a calamity, however, if it coincides with apprehensions and uncertainties about one's self.

This competitiveness, the author points out, is in direct contradiction with the Christian ideals which declare that it is selfish to want anything for ourselves; that we should be humble, turn the other cheek, be yielding. For this contradiction there are only two solutions within the normal range: "To take one of these strivings seriously and discard the other; or to take both seriously with the result that the individual is seriously inhibited in both directions."

There are many things to commend in this book and many things to criticize. The definition of the normal and the neurotic has a vagueness which is inherent perhaps in the subject matter and in the present state of knowledge.

Nevertheless, there is a great danger in making the term neurotic stand without a well defined substantive except the hazy one of character and person lity alteration without symptoms. A thorough search of any personality would disclose contradictions, dysharmonies and disorders of the "neurotic" type. There may be neurosis without symptoms, but until we know more about the neuroses it is hazardous to consider anyone neurotic who has no symptoms. In no other field of medicine than psychiatry, in no other field of science, would any such vagueness of definition be tolerated or given respectful hearing. To neuroses themselves, as they become defined in symptom groups, are amenable to something corresponding to scientific discussion. Without the solidity of symptom-complexes, we deal with adjectives unrelated to nouns, we live in too rarefied an atmosphere and too vague a flow of thought for anything really worthwhile from a scientific standpoint. Literary agility, subtlety, skill in manipulation, flourish under such circumstances and nothing can be proven or disproven. The race then lies to the verbally agile and the ingenious, but not to the scientific.

Moreover, there has always been competitiveness; there has always been fear; and every culture from time immemorial has by its taboos, inhibitions and injunctions contradicted the basic trends of the viscera and the personality. Probably of more new importance than the competitiveness and the contradictions present in our culture are the disturbances of rest and recuperation which are part of the stimulation given to man by his new instruments. Night has been turned into day by the electric light, and the annihilation of distance means that we can steep ourselves in the emotions engendered, let us say, by the conflict in Spain at the moment the conflict itself is raging, so that we become witnesses of every tragedy which is going on in our turbulent world. The conflict which takes place within the human being expresses itself in the case of those who succumb sooner or later by a disturbance of physiology, by an annihilation or diminution of rest; by disturbance in the appetites; by paresthesiæ; by altered activity of mind and body, in a word, by neurosis. For the time being we may rest content with the effort to study these basic alterations, and we need above all things to build up a physiology of the changes, so that psychiatry will not remain a place for the exercise of ingenuity, but a scientific field.

Meanwhile, it is of hopeful importance that a psychoanalyst has declared that other factors besides the "genetic" (which, by the way, is a wrong use of the term genetic) are of importance; that man does not only live in the past of his own life history but also in the present; that etiology, so far as neurosis is concerned, does not inhere only in the complexes of childhood and infancy, but that the social structure operates to produce dysharmonies in the more obvious human relationships, and thus becomes a potent force in the production of the neuroses. Add to this the fact that the style of the book is excellent, and the manner of presentation frank and vigorous, the result is a book worth reading by even the case-hardened Freudian and the equally hardy and prejudiced non-Freudian.

ABRAHAM MYERSON, M. D.,
Boston.

EUGENICAL STERILIZATION. By *Abraham Myerson, M. D., James B. Ayer, M. D., Tracy J. Putnam, M. D., Clyde E. Keeler, Sc. D., Leo Alexander, M. D.* (New York: The Macmillan Co., 1936.)

In May, 1934, the American Neurological Association appointed as a Committee for the Investigation of Eugenical Sterilization the gentlemen whose names appear as the authors of this book. The work of the committee was subsidized from a grant from the Carnegie Foundation. After two years of exhaustive research and painstaking work the committee has presented its findings in this 200-page volume.

A careful summary of this report, embodying its principal findings, conclusions and recommendations was prepared on request by Dr. Abraham Myerson, chairman of the committee, and appeared in the November, 1935, issue of this JOURNAL. It is therefore unnecessary to offer here an extended review of the book, and readers are referred to the article just mentioned. There can be no doubt as to the great value of this study which has surveyed the world's literature on the subject, and has endeavored to take into account the known facts of genetics and of the inheritance of the several conditions called mental diseases. The authors make plain the vast difference between the theories of eugenics and the established data of genetics, and demand that social planning and legislation shall be based upon the latter.

In their conclusions they recommend that any law concerning sterilization passed in the United States under the present state of knowledge should be voluntary and regulatory rather than compulsory; that any such law should apply not only to patients in state institutions but also to those in private institutions and those at large in the community. They suggest the type of board which should be set up for giving effect to such legislation.

Specifically the committee recommends sterilization in selected cases of certain diseases and with the consent of the patient or those responsible for him. They recommend that such selective sterilization be considered in cases of the following diseases (arranged roughly in the order in which sterilization would appear to be indicated):

(1) Huntington's chorea, hereditary optic atrophy, familial cases of Friedreich's ataxia, and certain other disabling degenerative diseases recognized to be hereditary.

(2) Feeblemindedness of familial type.

(3) Dementia præcox (schizophrenia).

(4) Manic-depressive psychosis.

(5) Epilepsy.

At the end of the volume will be found a 20-page bibliography and author and subject indices.

C. B. F.

In Memoriam.

JAMES RAMSAY HUNT.

1874-1937.

Dr. J. Ramsay Hunt died at his home in Katonah, N. Y., on July 22, 1937, after a long illness. Until the end he maintained that keen interest in neurology and psychiatry which had characterized his long and useful career in the practice of medicine.

Dr. Hunt was born in Philadelphia in 1874 with a prestige of medicine behind him, for his great-grandfather, William Hunt, was a surgeon and his grandfather, Jacob Hunt, was a physician. Dr. Hunt received his education first at the Friend's Central School in Philadelphia and later at the University of Pennsylvania where he received his degree of M. D. in 1893. Following this he spent some years in post-graduate study in the Universities of Vienna, Berlin and Paris and then returned to New York to the private practice of neurology and psychiatry.

Dr. Hunt's first interest was neurology and he did pioneer work in the diseases of the extra-pyramidal system. His writings on the geniculate ganglion syndrome, the pallidal system, dyssynergia cerebellaris myoclonica (Hunt's disease), and the static and kinetic systems of motility opened up new fields in the study of obscure nervous diseases. In his later years he turned away somewhat from organic nervous diseases and interested himself more in the big problem of the psychoneuroses. In carrying out his work in this new field he founded the neuropsychiatric division of the Neurological Institute of New York and was very active in furthering this service where psychoneurotics could receive adequate study and care.

He started his work as a teacher in the Cornell University Medical School in 1900 when he was appointed instructor of neurology, which position he held until 1910. At this time he went to the College of Physicians and Surgeons, Columbia University, as associate professor of neurology. He resigned this post in 1915 but

was appointed again by Columbia University as clinical professor of neurology in 1924, and in 1931 as professor of neurology which position he held at his death.

Dr. Hunt was throughout his life connected closely with the scientific societies and they offered him many honors. He served as president of The American Neurological Association, The American Psychopathological Association, The Association for Research in Nervous and Mental Diseases and the New York Neurological Society. He was a member of The American Psychiatric Association, the Association of American Physicians and corresponding member of the Société de Neurologie de Paris. During the war he served as consulting neuropsychiatrist to the Officers' Training School at Fort Myer, Va., and later in the same capacity in the A. E. F., France, with the rank of Lieutenant-Colonel. In 1931 his alma mater bestowed on him the honorary degree of Sc. D.

To Dr. Hunt's many friends in neurology and psychiatry his passing has been a personal loss. We knew him to be a sincere worker, a clear thinker and a loyal friend. The sincerity of his research work and the scholarly clearness with which he wrote made the value of his scientific productions. His kindly personality, his genial sense of humor, the warmth of his friendship made for us the Ramsay Hunt we all remember with affection.

LOUIS CASAMAJOR, M. D.

CORRELATIONS OF BEHAVIOR AND NEUROPATHOLOGY IN A CASE OF CEREBRAL PALSY FROM BIRTH INJURY.

§1. Introductory.

The importance of bringing into correlation functional and pathological findings in the field of human neurology needs no emphasis. In the present instance the senior author, over a period of almost ten years, made repeated studies of the behavior development of a child presenting severe athetosis and recurrent spasticity.

* Several members of the staff of the Yale Clinic of Child Development participated in the study and the training of A. C. We are particularly indebted to the observations and assistance of Elizabeth Evans Lord, Burton M. Castner, and Ruth W. Washburn. Mrs. Mary McGrath had immediate charge of the intensive educational program, when A. C. was 10 years of age.

This boy came to necropsy at the age of 14 years and the brain, spinal cord and meninges were minutely investigated (by H. M. Z.). The following report summarizes with interpretive comment both the neuropathological and behavioral features. The psychological aspects of the case are particularly noteworthy because the neural lesions were well defined and uncomplicated. Anatomic study of the nervous system disclosed a typical picture of " status marmoratus " in the basal ganglia.

This condition was described by C. and O. Vogt, who found that the striatum in each of their eight patients had the appearance of marble due to the alternation of light and dark zones. The marble-like appearance, from which the syndrome got its name, was produced by patches of gliosis and delicate myelin fibers in a striatum which was nearly completely lacking in ganglion cells. The concomitant clinical picture was described as appearing at or soon after birth and consisted of epileptiform attacks, muscular spasticity, athetosis and generalized choreiform movements, compulsive laughing or crying and lack of mental development. Jakob included the description of a similar case in his monograph on extrapyramidal diseases.

With the account of Bielschowsky's case, it was recognized that *status marmoratus* is not restricted to the striate body, but may be present in the cerebral cortex as well. Likewise, it soon became apparent that the lesions were not necessarily a developmental anomaly, as the Vogts believed, but that they might be acquired at or some time after birth. This opinion has recently been expressed by Löwenberg and Malamud in their study of four patients. Whereas the histopathology and the etiology of this condition are discussed exhaustively in the literature, the behavioral data without exception are inadequate.

DEVELOPMENTAL HISTORY.

The patient, A. C., was born after a prolonged labor of 24 hours, at full term, weight 10 pounds, attended by a physician who was unaware of the difficulties of two previous parturitions. Two sisters alive and well, age 12 and 13 years at the time of his birth, had also been born in dystocia. There were two miscarriages. The patient's head was in sight at 7 a. m.; with delivery at 3 p. m.

The head was misshapen but no instruments were used and there were no evidences of hemorrhage, rash or desquamation. At birth, breathing was weak; artificial aid to respiration and hot water stimulation were administered; the breathing during the night was irregular. At about midnight the infant showed twitching of the left cheek, but he was neither limp nor rigid. Forty-eight hours after birth, he had convulsions of unknown extent and duration, possibly limited to the right side and associated with flaccid paralysis of that side. He was deeply cyanosed; his fontanelles bulged; there was marked bilateral internal strabismus. He failed to suck or swallow and was fed with a medicine dropper for ten days.

To the surprise of the physician the patient slowly improved at the end of two weeks and he was then able to take the breast. He took notice of his surroundings at about five months. The paralysis apparently disappeared and the child's development was regarded as relatively normal until about the age of six months when spasticity was noted particularly on the right side. Dentition started at about eight months, the left side distinctly taking the lead.

The facies at favorable moments wore an alert and friendly expression which gave an aspect of normality. It is a remarkable developmental fact that even at the age of six months A. C. showed a strong drive to reach for objects and fussed because of his inability to attain them. But his motor disabilities proved to be profound. He was never able to fully balance his head; nor to acquire control of the muscles of swallowing and of articulation. He was never able to sit up alone, to stand or to secure an object by self-directed prehension. He rotated his head and rolled on the floor at the age of one year. He supported his own weight when held by his mother at the age of three years and four months. His internal strabismus underwent almost complete spontaneous correction during the first year, and his oculomotor control was least impaired. Spasticity and athetotic movements involving face, arms and legs increased during the first four years. Contracture became more marked and the athetosis had shown very slight amelioration before he died from appendicitis near the age of 14 years.

§2. Early Behavior Status.

The patient came to our notice at the age of four years. In body length and weight he was slightly in advance of the average

for his age. He had suffered only a few minor illnesses; slept well, and was not markedly fatigable. His features and torso were well formed. His countenance was normal, attractive, and expressive for brief intervals when not in the throes of involuntary activity. He could not hold up his head, sit up, creep, reach nor manipulate. At times he was quiescent, but under the least excitement, arms, head, fingers, also face, mouth, tongue—and to a lesser degree, legs and toes—went into apparently aimless extensions, flexions and rotations, with antagonistic muscles shifting their ascendancy. Occasionally the double athetosis became extreme, the movements on the right side being most pronounced and abrupt. There was recurrent spasticity. Crossing of the legs disappeared on relaxation and was not associated with marked contracture. Right and left abdominal, cremasteric and Babinski reflexes were present; eye grounds and pupillary reflexes were normal; knee jerks were variably moderate or hyperactive. Spasms of the pharyngeal, lingual and associated muscles made swallowing, mastication, and phonation difficult. There was frequent salivation. These latter characteristics combined with the motor disability had led a previous physician to a diagnosis of mental deficiency.

Close study of the behavior patterns of this boy showed, however, that in no true clinical sense could he be classified as feebleminded. His general somatic development, and particularly his personality traits, indicated that he was potentially of normal or even superior capacity and that the birth injury had inflicted a selective rather than a pervasive damage to his behavior equipment. In spite of the extreme motor discoordinations, his personality remained relatively well integrated with well sustained and discriminating emotional attitudes toward his social environment. He won for himself a circle of friends among children of his own age, who visited him and managed to play with him on their own level of social maturity.

These personality characteristics must be given important weight, if we are to arrive at a just correlation of the behavior picture and the neuropathological picture. He was able with great efforts to express yes and no by crude head gestures which were so ungoverned that they resembled each other, but which his family could sometimes differentiate. He was practically unable to combine a consonant and a vowel, but he managed to make a few

slightly distinctive vowel sounds associated with different meanings. A single brief incident must suffice to convey an impression of the most normal aspects of his behavior.

He liked to be propped up at the window so that he could participate in the life about him. On one occasion (age four years) he was watching some construction work on the street. He saw the neighbors' children having great fun crawling through the big drain pipes lying by the side of the road. He became greatly interested. Though unable to articulate he ejaculated " I-I " in no uncertain terms. This was his most vivid utterance used whenever he was able to muster it, in all situations in which he wished to call attention to his own stake in any event or plan. It was his unmistakable way of indicating that *he* wished to crawl through those pipes, too. Doubtless he had enough " autocriticism " to know that he could not crawl; but he also had enough imagination and drive to desire all possible experience, from sliding down a banister to riding horseback. With the aid of his sisters he was brought to the entrance of the pipe, and by their combined efforts and his struggling cooperation, he was propelled through the big drain pipe tunnel, to his great delight.

His personality sense was so robust that he wished to have the same school-going status as his playmates. Partly for this reason and also to determine his learning capacities we devised from time to time " lessons " in " reading," " drawing " and " number work." There was little difficulty in enlisting a pupil attitude. By the age of seven years he gave sustained attention for 30 minutes in a reading lesson.

The accompanying graph summarizes the behavior status of A. C. at the age of 56 months. Various items in four major fields of behavior are rated on the basis of the Yale norms of behavior maturity. It is evident at a glance that the extreme defects in the motor field have not resulted in a comparable degree of retardation in other fields of behavior. But even the low ratings in motor performance need qualification in interpretation. (See Fig. 2.)

A normal infant, four months old, lying on his back can hold his head in the midposition, watch intently a rattle dangled above his chest; and can moreover bring both arms to the midline, close in on the rattle, and grasp it. A. C. was never able to execute this most elementary act of prehension; and yet he used his oculo-

motor muscles with alertness and perceived incongruities in a caricature drawing of a man. The limitations of his experience in manipulation and locomotion did not inflict a drastic arrest of his perception and appreciation of spatial relations.

Likewise in the field of language. His actual utterance was at a meager, infantile level; but his comprehension of words and even verbal nuances seemed to be near a normal level. In number comprehension he distinguished between two and three telephone rings and probably had a concept of four. His humor sense, his amusement at accidental absurdities in the home life, his story and play interests, all suggested a considerable approximation to normality in the perception and appreciation of social relations.

§3. Later Behavior Development.

On the basis of the behavior picture at 56 months of age, it was not easy to predict the subsequent course of development. To what extent were the foregoing indications of normal though atypical behavior characteristics borne out in the subsequent nine years of life? This question is of theoretical interest from the standpoint of neurological development. It also has practical implications for the problems of treatment and of corrective education.

Even before the age of five years, as already suggested, A. C. showed a certain eagerness to be going to school. For this reason his early contacts with the clinic had been converted into blackboard lesson periods which served him as a substitute for school, and gave us an opportunity to observe his response to the teaching of words and numbers. Ordinary methods could not be used. We had to rely on his rather ambiguous yes-no head gestures, on crudely differentiated phonations, on facial expressions, to establish communication. With the aid of the blackboard it was possible to present words, incomplete sentences, incomplete drawings, numbers and sums. By devising games it was possible to test with varying degrees of certainty his powers of recognition and memory.

In a few sessions he learned to distinguish simple words like *ball, cat, hat, man.* By the age of seven years he had learned to recognize with variable success perhaps 35 words. In listening to stories his interest had advanced from *Black Sambo* to *Three Bears* to *Grimm's Fairy Tales.* There was hope that with greater

FIG. 1.—A. C. at advancing age levels: 9 months; 14 months; 3½ years; 5 years; 13 years.

FIG. 2.—Growth graph showing the developmental status of A. C. at the age of 56 months.

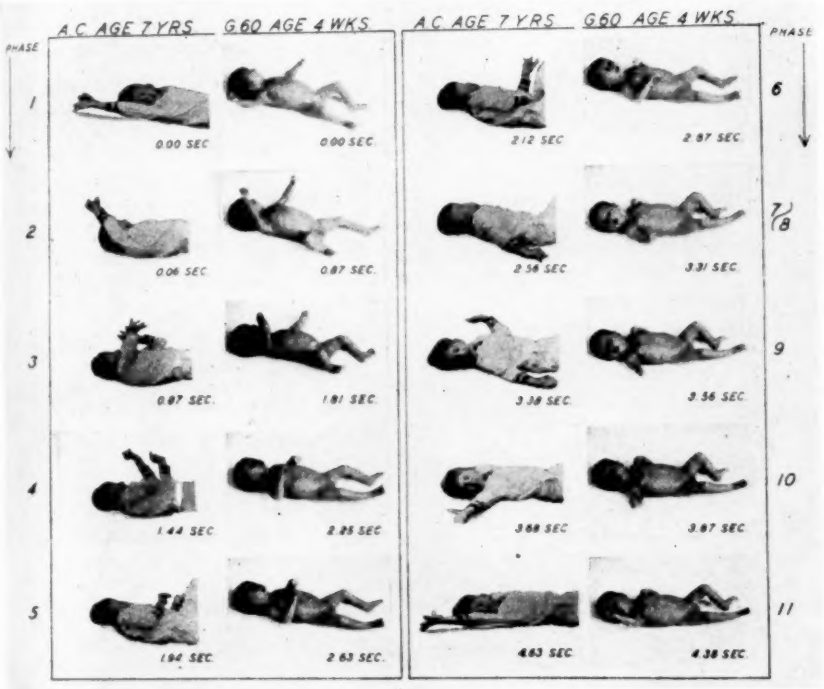

FIG. 3.—Comparable consecutive phases of the athetotic action pattern of A. C. age 7 years and of the spontaneous supine action pattern of a normal infant, G60, age four weeks. Eleven phases with the elapsed time indicated in seconds are shown side by side in vertical columns.

FIG. 4.—Micro-photographic section. *Status marmoratus* of lenticulate and thalamic nuclei (phosphotungstic acid-hematoxylin stain).

FIG. 5.—Micro-photographic section. *Status marmoratus* of lenticulate nucleus (Kulschitzky stain).

FIG. 6.—Micro-photographic section. Region in putamen showing poorly formed, coarse and delicate myelin fibrils (Kulschitzky stain).

maturity he might learn to read. He had even made some progress in holding a large crayon thrust in his hand, but had made no gain in directing it. His attention span and his social maturity showed a slight, steady increase. His " lessons " at home and at the clinic were irregular and occurred about once a week. At the age of 8½ years his attainments were reviewed and it was concluded that he showed essentially the same ability to deal with printed words and numbers which he had shown at the age of five years. He gave no convincing evidence that in power of abstraction or true ability to read he was equal to the intellectual level of a normal six-year-old.

For another year his " schooling " continued in a rather desultory manner. His articulation improved slightly. At favorable periods of relative relaxation he could " pronounce " numbers up to 10, with crude phonetic discrimination of the vowel values. He had scarcely any command over consonants. At the age of 9½ years he had a recognition reading vocabulary of about 50 words.

In spite of the limitations revealed by this rate of progress, it was decided that the potentialities of intellectual development could only be determined by a more systematic teaching program. It might well be that A. C.'s training thus far had been too incidental and irregular to overcome his profound handicap. A skilful teacher was engaged over a period of six months to give training five times a week in two-hour sessions. As a stimulus and to satisfy his ambition to attend a real school, the lessons were conducted in a separate room of an elementary school. A reading frame was placed athwart his perambulator; interest provoking devices were used, but the earlier playful approach gave way to a more serious attack. He made a good adjustment to the new régime. He soon was scanning with his eyes seven successive pages of the book supported in the reading frame. The eye movements accompanied by vocalization, inflections, and tongue movements gave the appearance of silent reading.

His behavior and his story interests were more mature than they had been. By the end of the six months he increased his reading vocabulary to about 100 words. But again it was not clear that he read with full insight. His progress in simple number operations was meager. He showed only occasional spontane-

ous interest in reading by himself at home. The significance of these limited responses to more intensive training will be discussed later.

During the four remaining years prior to his death he made only slight academic gains. He matured however in his emotional life and his social interests. He learned to play a simple game of checkers, attending closely for 20 minutes. He named his moves by vocalizing the number of a checker and indicated right or left by yes or no. He showed a preference for boy companions of his own age, and also gave signs of preadolescent bashfulness. He could read the clock and was permitted to play the part of monitor in a rural school room which he attended daily for an hour.

His neurological symptoms were only slightly ameliorated in spite of the fact that physiotherapy treatments were faithfully continued for years. His cooperation in the muscle training was excellent both at home and at the hospital, and he showed morale in enduring the pain which resulted from manipulations to overcome contracture. The spasticity of arms and hands somewhat diminished. He learned to open his hand voluntarily on many occasions. He was able to sit for a half hour supported by pillows, without falling. Salivation decreased and articulation was slightly improved. In the intellectual sphere his rate of later development was distinctly slower than it had been during the first five years of his life. There is evidence that in the emotional and social spheres his development was slowly advancing and that he would have continued to mature during the period of adolescence.

§4. The Action Pattern of Athetosis.

The outstanding characteristic of the observable behavior of A. C. was his extensive, ever recurring athetosis. He appeared to be dominated by athetotic movements, which, nevertheless, contained or concealed whatever controlled motor adjustments he might muster. From a neurological and also from a psychological viewpoint, it seemed important to analyze the nature of these athetotic movements as clues to brain states.

Athetosis is none too clearly defined in the literature. The available descriptions show a wide range of emphasis and specification. In general these descriptions are colored by the vague concept of

"overflow" and stress the aimlessness of the movements with such phrases as "mobile spasm," "wild wriggling and twisting," "convulsive flood of energy," "irregular, choreiform, vermicular," "chaos of writhing movements," etc. Says W. Russel Brain: "In bilateral athetosis the patient exhibits frequent grimaces resembling caricatures of normal facial expressions of all kinds." Wechsler characterizes double athetosis as "mass or widespread movements involving practically all of the muscles, especially the hands, feet, and face."

Are athetotic movements as incoherent and formless as many of these characterizations suggest? We have at our disposal a method which should help us to answer this question, namely cinemanalysis.* The cinema records all movement in rapid registrations (16 photographic frames per second in the ordinary 16 mm. film). Naturally the cinema "sees" more comprehensively than the most acute clinical eye. It registers completely and remembers infallibly simultaneous attitudes of head, trunk, arms, legs, eyes, fingers, face. Each frame crystallizes a movement of behavior in its total synthesis and permits us to study this moment as a frozen section of motion. Cinemanalysis consists of a sequential analytic study of such cinema frames to define the successive phases of any behavior in terms of time and space. By the method of cinemanalysis it is possible to determine the presence or absence of pattern in the disordered motility of athetosis.

For study we had available approximately 325 feet of film depicting athetotic behavior at the 7, 10, and 13 years of age levels. These cinema records were inspected with the aid of the projection desk. Special attention was given to the movements and positions of the arms and head. Numerous tracings were made showing successive phases of the moving members. The tracings and descriptive notes were then reviewed to ascertain whether there

*The method of cinemanalysis is described at length in references 6, 7, 8. A projection desk is used to facilitate analysis. A projector under convenient control throws a succession of small images on a viewing glass incorporated as a window in the working surface of the desk. By turning a crank we view the images in full motion or slowed motion, forward or reverse. By arresting the crank any frame may be studied as a stilled pattern phase and the whole record may be subjected to frame by frame analysis. A counter registers each frame (time value: 1/16 sec.) as it passes through the projector.

were any recurring trends in the sequences and configurations of activity. After this review, a similar study was made of the spontaneous head and arm movements of supine normal infants at the 4, 6, 8, and 12 weeks levels of maturity.* The preliminary results of this comparative analysis, as summarized below, clearly show that a large part of the athetotic behavior falls into definite patterns which recur repeatedly at one age and which also remain from age to age.

An action pattern is a total movement which occurs consistently in a given situation and exhibits a characteristic course. This course is manifested in an orderly sequence of attitudes or pattern phases in the moving members. In the present instance, we shall deal chiefly with the athetotic movements of head and arms while the subject is in either the supine or supported sitting position. Cinema records were made at 7, 10 and 13 years. One characteristic action pattern was displayed at each of the three age levels.

When inspected by cinemanalysis the typical cycle of action revealed itself in 11 distinguishable pattern phases which will be presently described. The tenth phase in this sequence is of special significance, because it is equivalent to the tonic-neck-reflex (t. n. r.) which is the most prominent behavior pattern in the repertoire of the normal supine infant during the first 12 weeks of life. This pattern bears some resemblance to a boxing attitude: the infant holds his head averted to one side, the arm on that side is maintained in outward extension, the opposite arm is flexed so that the hand rests near the occiput. Magnus has demonstrated a similar pattern in quadrupeds. This postural set plays a fundamental rôle in the mechanics and the developmental morphology of early infant behavior.

* The supine behavior of these normative infants is delineated in Gesell, A. *et al.: An Atlas of Infant Behavior: A Systematic Delineation of the Forms and Early Growth of Human Behavior Patterns,* illustrated by 3200 action photographs in 2 volumes. Volume *One: Normative Series* (in collaboration with Helen Thompson and Catherine Strunk Amatruda), pp. 1-524. Volume *Two: Naturalistic Series* (in collaboration with Alice V. Keliher, Frances L. Ilg, and Jessie Jarvis Carlson), pp. 525-922. New Haven: Yale University Press, 1934. Pp. 922. (See Volume One, pp. 50-67.) See also Gesell, A., and Thompson, H.: *Infant Behavior: Its Genesis and Growth.* New York: McGraw Hill Book Co., Inc., 1934. Pp. 333. (See pages 49-61.)

The t. n. r. attitude proved also to be an important feature in the behavior of A. C. Its presence was obscured by the lively athetotic movements, but when the cinema films were quantitatively studied it was found that he was in a t. n. r. posture from 41 to 56 per cent of the recorded time at 7, 10, and 13 years. It was also noted that the head generally took the lead in initiating the t. n. r. posture. In eight instances out of 11 the head movement occurred palpably in advance of the appropriate arm extension. In another instance it occurred slightly, but perceptibly, in advance. In one instance the extensor arm and in another instance the flexor arm took the lead. But in no instance was a reversed t. n. r. attitude assumed. The head was always directed toward the extensor arm. This suggests that the proprioceptive stimulus in the neck, as adduced by Magnus, was operating to bring about the natural reflex.

The typical athetotic pattern of A. C. displayed the following sequence of phases, which occurred (as does the normal t. n. r) in either left or right armed versions:

1. The active arm is extended above the head, elbow close to the head; the head is rotated facing toward the extended arm; the contralateral arm remains flexed at the shoulder level.

2. The head rotates to mid position; the arm, still extended, swings across the face with a downward motion; the flexed contralateral arm moves slightly downward.

3. The head remains in mid position; the arm flexes slightly and continues down across the face; contralateral arm moves downward so that it is flexed at waist level.

4. The arm continues downward, still flexed; hand comes above waist level; contralateral arm is in a similar position.

5. Active arm continues downward, still flexed; hand comes to waist level; contralateral arm in same position as active arm.

6. Active arm continues downward; contralateral arm starts upward.

7. Active arm extends as it moves downward; contralateral arm, still flexed, moves upward.

8. Active arm comes to full downward extension beside the body; contralateral arm moves upward.

9. Head rotates toward the side again, facing active arm; contralateral arm flexed upward with hand at shoulder level.

10. Active arm in full extension comes to shoulder level; head is turned so that face is toward extended arm; contralateral arm is flexed with hand near occiput (t. n. r. posture).

11. Extended arm moves upward in extension, above and close to head; contralateral arm remains as in phase 10, thus reinstating phase 1 when the cycle is repeated.

The above sequence may be envisaged as a slashing windmill reaction emerging out of and returning to a basic t. n. r. attitude (phase 10). Phase 11 is a transitional phase which usually reinitiated the cycle. Variations of the typical sequence were confined to the terminal phases (10 and 11) which were sometimes repeated as " fragments "; and to phases five and six, in which the downward movement was replaced by an upward flexion of the forearm, bringing the hand up to the chin. This substitution of movement might occur only once, or under excitement two or three times in close succession, simulating an uncontrolled perseveration, whereupon the subsequent phases resumed their typical course.

PATTERN PHASE ANALYSIS OF THE ATHETOTIC ACTION PATTERN.

(Duration Indicated by Frames.)

	Specimen.			
Phase.	One.	Two.	Three.	Four.
1	0	0	0	0
2	7	8	10	9
3	5	7	13	3
4	3	8	5	3
5	4	8	3	10
6	3	7	11	5
7	7	2	8	6
8	6	9	6	5
9	8	4	2	8
10	17	3	5	12
11	10	10	11	4
Total no. of frames	70	66	74	65
Duration of total sequence in seconds	4.6	4.2	4.10	4.1

A frame by frame cinemanalysis of the athetotic action pattern at the age of seven years was made to determine the time values of the eleven consecutive phases. These values are given in the table above. Four specimens of the pattern were analyzed. The duration of each phase is indicated by the number of frames listed in the vertical columns. The total duration for the entire action pattern is also indicated in seconds. Although the time values for single phases varied slightly, the total durations for the total cycle showed a surprising degree of consistency.

Most of the observable behavior of A. C. conformed to the basic athetotic pattern described above. When the typical cycle was not

in evidence either in part or as a totality, the patient was either quiescent or the activity consisted in trunk torsion, bilateral adduction of the arms and simultaneous drawing up of the legs.

The typical athetotic cycle was observed both in the spontaneous supine behavior and also under the prolonged stimulation of a stimulus object which was dangled within reach of the subject while he strove to prehend it. It is significant that the basic athetotic pattern lost none of its integrity under the stress of apparent voluntary effort.

§5. Comparison of Athetotic and Normal Behavior Patterns.

In order to better define the distinctive features of athetosis we made a comparative study of the spontaneous supine behavior of normal infants from 4 to 12 weeks of age. Reviewing our normative records of these infants we found amazing correspondences between the athetotic and the infantile movements. The reader can gain some impression of these correspondences by examining the accompanying Fig. 3, in which comparable consecutive phases are depicted side by side. Both with respect to sequence and total elapsed time there is a high degree of correspondence. In general the supine behavior patterns of A. C. at the age of seven years most closely resembled those of a four weeks' old normal infant. Such an infant thrusts his arm in upward extension and makes slashing, windmill motions which momentarily are strikingly like those of A. C. Likewise the characteristic t. n. r. interdependence of the active arm and the head position is more clearly revealed at four weeks than at the later ages. As the normal infant matures, the t. n. r. loses its unitary simplicity and the various components, namely head rotation, arm extension, contra-lateral arm flexion, and leg extension, assert themselves with partial independence.

Interestingly enough this tendency expressed itself also in A. C. as he grew older. A. C. at 10 years still displayed the early windmill slashing but in several respects the postural behavior more closely approached that of the normal eight weeks infant. At 13 years of age A. C. showed a few approximations to the type of supine behavior found in a normal infant at 12 weeks. His arms came less frequently into full downward extension, and remained above the waist level.

When the athetotic and the normal behavior patterns are viewed in full motion on the screen, significant contrasts emerge.* In synergy and smoothness of performance, A. C. never equalled the normal infant. A. C.'s movements were, in comparison, stereotyped, abrupt and jerky. In spite of their temporal jaggedness, however, they pursued in space a route similar to that of the infant. When slowed down (through time magnification) the athetotic pattern acquires a spurious fluency. These contrasts, however, should not obscure the neurological implications of the correspondences established between the athetotic and the normal infantile patterns of behavior. Before attempting further interpretations, the neuropathological findings will now be summarized.

§6. Neuropathological Findings.

Macroscopic.—The cerebrospinal leptomeninges were everywhere delicate and translucent, being free from exudation and blood pigment deposition. They were not unusually adherent to the underlying nervous parenchyma. All the cerebral convolutions were well developed, and the cerebral sulci were normal in width and depth. There were no anomalous formations in any of the larger pial vessels. All the cranial nerves appeared to be normal. The pituitary body was wanting in the specimen, but the infundibular stalk was in place behind the optic chiasm and was not unusual in any respect. The pineal body was of the usual size, color and consistence.

Numerous sections of the cerebrum revealed no abnormalities in the cortical gray matter as regards the width and color of the laminæ. The cortex was well defined from the subcortical white matter. The centrum ovale presented the usual color and consistence. When sectioned in a horizontal plane the upper half of the left basal ganglions contained striking changes in the lenticular and thalamic nuclei. The changes consisted of gray and white irregular mottlings which were associated with unusual firmness of the involved nuclei. Changes similar to these were also noted

*A 16 mm. cinema reel, 225 feet in length, has been edited to show the typical behavior of A. C. at 7, 10, and 13 years and to delineate by comparative examples the spontaneous supine behavior of a normal four weeks' old infant.

in the right basal ganglions at a similar level. The globus pallidus on either side appeared to be intact, the lesion in the lenticular nucleus being confined to the putamen. A similar but less extensive change was present in both caudate nuclei. The lesions seen in the basal ganglions were typical of the macroscopic picture of *status marmoratus*. The corpora quadrigemina and red nuclei appeared to be normal. Although poorly pigmented, the substantia nigra was well defined and of average size. Nothing abnormal was seen in the cerebellum, pons and medulla. Multiple transverse sections of the spinal cord failed to reveal any definite lesions.

Histologic.—There were no deviations from the normal in the cerebral and spinal leptomeninges. The pial and parenchymal vessels also presented no abnormalities. The cortical cyto-architecture of the frontal, temporal and parts of the parietal lobes was altered as a result of destruction or lack of development of the ganglion cells. The third and fifth laminæ were especially affected, the paucity of ganglion cells in these layers being rather conspicuous even with low magnifications. Few changes of this variety were present in the cortex of the occipital lobes. There were no definite glial scars in any part of the cortex.

Dense glial scars were demonstrable in certain parts of the thalamus with victoria blue and phosphotungstic acid-hematoxylin stains (Fig. 4). The scars were usually stellate in shape and of small size, but occasionally they were confluent and large. They were most conspicuous in the pulvinar and in the ventro-median thalamic nuclei. Although present around blood vessels, they appeared to have no particular predilection for the vascular system. In Kulschitzky preparations there were found fine and coarse myelin fibers in the scarred zones which were so arranged as to form the well recognized picture of *status marmoratus* (Figs. 5 and 6). The geniculate bodies were not altered in this manner. The pallidal nuclei showed but a minimum involvement of this type; this was also true of the tuberal nuclei of the hypothalamus, but the periventricular gray and the nuclei of Luys were more extensively altered. The internal capsules were normal whereas the putamina were strikingly scarred and the caudate nuclei only slightly less so. The red nuclei and substantia nigra were essentially unchanged.

There was no evidence that this process, *status marmoratus,* was a progressively destructive one. There were no fat granule cells and no reactive glia. The scars were associated with an increase in the small round oligodendroglia.

The pons, medulla and cerebellum, as well as the spinal cord, were esentially normal.

§7. Tabular Summary of Neuropathological and Behavioral Findings.

The table on pages 521 to 525 provides a condensation of the neuropathological and behavioral findings, for the convenience of the reader. The left hand column lists the various structures of the central nervous system and their neuropathologic condition; the middle column, the normal function ascribed to these structures; the right hand column, the actual functions observed or inferred in A. C. The letters *N* and *D* (sometimes shaded by plus or minus signs) indicate respectively a normal and a defective (or deficient) histological condition. In the right hand column the presence, absence, or questionable status of a given function is indicated by +, −, and ?. The middle column of ascribed "normal" functions is to be taken schematically rather than literally, as a basis of reference for interpreting the observed functions tabulated in the third column. It is not assumed, of course, that any one level or structure functions independently, without participation by other parts of the nervous system.*

§8. Interpretation of Behavior Characteristics.

With the foregoing data, both pre-mortem and post-mortem, before us, we may attempt to formulate an interpretive summary of the behavior characteristics with special reference to the neuropathological findings. These characteristics will be discussed in

* For a compact orientational discussion of neurological and psychological relationships, the reader may consult two companion articles which recently appeared in *The American Journal of Psychology* (April, 1937): Papez, James W., The brain considered as an organ: neural systems and central levels of organization. *Amer. Jour. Psychol.,* 1937, XLIX, pp. 217-232; and Bentley, Madison, The psychologist's uses of neurology. *Amer. Jour. Psychol.,* 1937, XLIX, pp. 233-264. See also Cobb, Stanley, A preface to nervous disease. Baltimore: William Wood, 1936, vii + 173.

For explanatory comments on the construction of this table see the adjoining page (p. 520).

STRUCTURE AND PATHOLOGY.		ASCRIBED NORMAL FUNCTION.	OBSERVED FUNCTION.
AUTONOMIC SYSTEM			
Cranio-sacral	N	Appetitive and organic sensation	+No deviations noted
Thoracico-lumbar	N	Preparatory emotion	+"Avalanche" emotion, blushing
SPINAL CORD			
Spino-medullary tracts	N	Proprioceptive impulses	+Present but uncontrolled for purposeful
Lateral spino-cerebellar	N	Proprioceptive impulses	+ movement
Interspinal	N	Proprioceptive impulses	+
Spino-thalamic	N	Pain and temperature	++(Exaggerated sensitivity)
Cerebro-spinal	N	Efferent conduction	
Rubro-spinal	N		Spastic crossing of legs
MEDULLA			
Nuclei, gracilis	N	First proprioceptive relay	+
Nuclei, cuneati	N	Sustained segmental reflexes	+
Medial lemniscus	N	Conduction to thalamus	+
Inferior olives	N	Relay for nuclei gr. and cuneatus	+
Nuclei, cranial nerves	N	Vegetative regulation	+Vegetative functions all relatively intact and under fair regulation

This table is continued on four following pages.

STRUCTURE AND PATHOLOGY.		ASCRIBED NORMAL FUNCTION.	OBSERVED FUNCTION.
CEREBELLUM			
Afferent tracts	N	Conduct proprioceptive impulses	+Complete absence of balance in sitting and standing. Intermittent head balance
1, dorsal; 2, nuclei gr. and cn.; 3, inf. olives; 4, lateral; 5, vestib.			
Efferent tracts	N—	Conduct impulses of coordination, modification and reinforcement	+But largely inoperative
Superior peduncles			—
Cerebellar-rubral			—
Cerebellar-thalamic			
Cortex	N	Energizes	++
		Checks and modulates	—Asynergia, arythmia
		Dual transformer (excita. and inhib.)	—Dysmetria, due chiefly probably to cerebral factors
MIDBRAIN			
Inferior colliculi	N	Subcortical center, hearing	++Hypersensitive to shrill sound; auditory localization present
Superior colliculi	N	Visual—motor responses	+Eye following. Discriminative eye
Nuclei: nerves III, IV		Oculo-motor impulses	+ movements in reading
Tegmentum-substantia nigra	D—	Regulation of postural tonus	—Basic postural tonus present but unregulated
Red nucleus	N	Maintains "lasting" posture back-ground on which cerebellar checks imposed	+?
Extra pyramidal tract	N—		—Basic postural set absent

Extra pyramidal tract	N—		—Basic postural set absent

relation to (a) autonomic behavior, (b) sensori-motor behavior, (c) intellectual abilities, (d) social behavior and personality.

(a) *Autonomic Behavior.*—The integrity of autonomic and vegetative behavior was preserved to a remarkable degree. There were no marked deviations in visceral, circulatory, respiratory, and pupillary reactions. Sphincter control was established at a fairly early age. Facial flushing occurred on exertion and also on excitement; but there was very little emotion of the floodgate or avalanche type. In spite of the cortical and thalamic damage above noted, A. C.'s emotional morale and affective organization were normal in their general character and vitality. The mamillary nucleus which is believed to govern feeding reactions and to participate in metabolic regulation apparently escaped unharmed by the prolonged ischemia. This was probably due to the extraordinary richness of the blood supply of this structure. Therefore notwithstanding severe damage to the putamen and caudate nucleus which also preside over feeding functions, A. C. was able to nurse at the breast at the age of two weeks.

Normally the reciprocal relations between the autonomic and higher centers are intimate. In spite of the intracranial damage these relations were in A. C. either only slightly impaired or the autonomic systems showed great capacity to function effectively in spite of defects in the normal neural connections.

(b) *Sensori-Motor Behavior.*—The nature of the limitations of A. C. in this field of behavior has been partly suggested in the analysis of his athetosis. His most fundamental and most crippling incapacity lay in the mechanisms of prehension, posture, and locomotion. Although the tactile and proprioceptive factors in these mechanisms were injured, the disablement was perhaps chiefly caused by the interruption of the efferent tracts. The energizing and to some extent the directive factors for prehensory and postural reactions were not wanting. Even at six months of age, A. C. showed an unmistakable propensity to reach,—a remarkable fact, for he never attained a neuromotor equipment to execute prehension, or to exercise the basic function of active touch.

In A. C. many phases of sensory experience were preserved. His vision was acute though we cannot be too sure that geometrically his perceptions were normally or precisely configured. His hear-

ing likewise was ordinarily acute. In spite of defective head control he showed proficiency in auditory localization. Taste, smell and passive touch and pain sensitivity were apparently normal. The neuropathological preparations show no impairment of the cerebral sensory areas for vision and only slight involvement of the hearing center. The calcarine area, ordinarily very susceptible to damage, was unharmed. The oculomotor muscles functioned and supplied important kinesthetic data.

In the field of grosser motor activity, however, his sensory implementation was probably blurred because of indistinct and obsessive kinesthetic experience. This inference is supported by the introspection of persons similarly though less severely handicapped. These persons report that their motor difficulties are greatly increased because the faulty motion formulæ of nonadaptive movements continually obtrude. The patient cannot achieve adequate (cortical?) engrams of movement unless the subcortical equipment is sufficiently accessible to permit progressive control of a given action system.

This is the condition of re-education. Engrams of movement are not localized as discrete mosaics in the cortex; but rest upon widely ramifying functional relationships with the lower levels of the neuro-motor equipment. The apex of such a ramifying system was almost completely isolated in the case of A. C. He failed to acquire articulate speech, the power to grasp and manipulate, and the capacity to sit, stand, creep or walk, for reasons which neurologically were essentially one and the same.

Voluntary control of postural adjustments and locomotion requires the equivalent of cortical engrams. The limitations of A. C. in the field of postural behavior can be best considered in relation to the tonic neck reflex—a fundamental " reflex " common to higher quadrupeds and man. In man this reflex figures in the ontogenesis of prehension as well as of body posture and locomotion.

The presence of the tonic neck reflex has sometimes been interpreted as a symptom of extensive damage to the central nervous system. This interpretation calls for some qualification. Our normative studies have shown that at the age levels from 4 through 12 weeks, two-thirds or more of normal infants in the supine position spontaneously assume a t. n. r. attitude of head and arms. At the age of 16 weeks the head begins to seek a mid position more

frequently; the t. n. r. retreats and gives way to more symmetric attitudes of the arms. At a transitional age, in a favorable normal subject, we have been able repeatedly to elicit in alternating succession a right t. n. r., a left t. n. r., a right t. n. r., etc., simply by slowly moving a hand back and forth across the infant's field of vision. This manœuver induced head following and with each rotation of the head to one side, the characteristic postural attitude ensued as though one were dealing with an automaton under photo-electric control.

Now the t. n. r. does not of course preserve a stereotyped invariability in the human infant. It undergoes important differentiations and complications with the maturation of postural behavior in general. It is also, probably, influenced by learning factors which perfect phasic or rhythmic executions of the patterns, manifested in wriggling, in extrication responses, in prelocomotor diagonal and creeping movements. Indeed, as the child grows older he displays two variants of the t. n. r., namely (a) the homolateral form (in which both extremities on the side to which the head is directed are in extension); and (b) the contralateral form (in which the arm only and the opposite leg are extended.) The latter prefigures the diagonal posturing at the basis of prone locomotion.

Cinemanalysis of the athetotic movements of A. C. at 7 to 13 years of age, shows that he repeatedly assumed the t. n. r. attitude, in the course of his spontaneous activity in the supine position. This might be interpreted to mean an arrest of postural development at an early infantile stage; for a comparable predominance of the t. n. r. response normally is characteristic of the first quarter of the first year. Such an explanation seems to us an over simplification. The t. n. r. asserts itself in A. C. when other more complicated reactions are impossible; because the neurological mechanism for the t. n. r. is so deeply entrenched that it does not require cortical controls to the same degree as do more advanced postural reactions. Accordingly, the "reflex" breaks through even when there are competing movements and meager cortical control. If the mechanism for prehension were as deeply entrenched in the central nervous system, the thalamic damage would not prevent occasional manifestations of a complete action pattern of prehension. No such manifestation ever occurred in the life of A. C.

either in periods of relaxation, of excitement, or of purposive endeavor.

This point of view helps to rationalize the t. n. r. phenomenon in so old a child. In spite of his intellectual and emotional capacities, A. C. was never able to bring his t. n. r. apparatus under control by higher centers. Which is a round-about way of saying that voluntary effort cannot command or modulate an action system if certain conduction paths are too gravely impaired. For similar reasons we would suggest that the athetotic movements are not entirely uncontrolled, erratic, aberrant. They are patterned, adaptive, and even integrated within their partial and piecemeal spheres. They are "lawless" only if viewed in terms of a single vertical hierarchy of universal integration.

(c) *Intellectual Abilities.*—The microscopic examination showed relatively few defects in the structure or architecture of the cerebral cortex. None of these lesions, including the necro-biotic mottling, is in itself inconsistent with a normal degree of intelligence. Whether there were ultra microscopic lesions not revealed by the pathological examination remains in doubt, even after a careful clinical study of the patient's mentality.*

The intellectual capacities of A. C. were estimated from time to time over a period of nine years. It is impossible to characterize these capacities by any single formula. As the graph of Fig. 2 indicates, his *adaptive behavior* (*i. e.,* his intelligence and general perceptiveness) at the age of 4½ years, was rated to be near a four year level. This is a fair description of his intellectual maturity, even if no special discount is made for his profound motor deficiencies. His discriminations of form, size, color, number, his attention span, his critical perception of success and failure, his recognition of incongruities and exaggerations, his insight into the meaning of social relationships—all betokened a mind which in its basic orien-

* D. Rothschild has presented evidence showing that in senile psychoses (and in arteriosclerosis) there is a lack of correlation between histologic changes and the degree of intellectual impairment. He attributes the discrepancy to differences in the capacity of different persons to compensate for cerebral damage. It is quite possible that similar factors operate in cerebral damages from birth injury. If so we should rate the compensatory capacity of A. C. as high, by reason of a naturally superior endowment. See American Journal of Psychiatry, Vol. 93, No. 4, 757-784, 1937.

tations approximated modes and even degrees of normality. He could in no sense be clinically classified as feebleminded, if this term is reserved for a generalized subnormal deficiency in mental adaptiveness.

At the age of 13 years the appraisal of the intellectual status of A. C. becomes more difficult. By this time the motor incapacities have taken a cumulative toll; they have taken their earlier toll with compound interest. At a concrete level his verbal comprehension remains relatively normal; he understands conversation about ordinary domestic affairs; but shows limited curiosity about affairs remote; he appreciates verbal incongruities and reacts to them with a sense of humor. But he does not show an abstract interest in words, nor has he demanded silent or loud reading to increase the scope of his information. Verbal auditory imagery is present but probably lacks normal context and support because of extremely meager kinesthetic data. In the management of numbers he makes his best showing when responding to problems about eight horses in eight stalls. (He always was passionately interested in horses.) But he reveals no interest in number concepts nor power of arithmetical abstraction. If it is true that proprioceptive impulses supply the major portion of the energy necessary to normal brain functioning, then we must conclude that in the spheres of symbolic and abstract thinking A. C. at the age of 13 years was seriously deficient. He lacked the ordinary kinesthetic carriers of notions and ideas. He suffered from a form of intellectual reduction due to faulty proprioceptive implementation. In spite of his intellectual poverty, however, he retained modes of thought and a certain perspicacity which clinically were inconsistent with either amentia or dementia.

(d) *Social Behavior and Personality.*—This approximation to a normal as opposed to a "feebleminded" mental organization is most convincingly shown in the field of social and emotional behavior. Here A. C. gives evidence of undergoing a steady progress toward mature levels of functioning. By the age of 13 years he has advanced in his play interests, he has changed progressively in his attitudes toward children and adults; he has shown characteristic preadolescent attitudes toward his mother. In spite of the inevitable dependency inflicted by his handicap, he displayed considerable morale in trying situations. To be sure he also shows traits which

would be regarded as "childish" in an unhandicapped child. But it seems important to stress here those behavior characteristics which prove that his central nervous system was not uniformly arrested by the ischemia which so extensively destroyed the functioning of his tactile-motor system. To a significant degree, even though imperfectly, the potentialities of neurological growth were realized in unimpaired regions of the brain.

§9. General Conclusions.

All this suggests that the tactile-motor elements of experience are not as crucial as is commonly supposed in the developmental mechanics of behavior. They are, of course, indispensible for normal living, but mental content and mental gestalt are not absolutely dependent even on kinesthetic data. The vitality and fullness of the mental life of A. C. were truly remarkable when we consider the paucity and the disfigurement of his kinesthetic experience.

How can we explain this significant approximation to a normal although impoverished realization of mental growth? A thoroughgoing motor theory of psycho-genesis would seem to be inadequate to account for the degree of mental growth which was attained. In many respects the handicap of A. C. was more devastating than that of Helen Keller. And he was denied those experiences in the field of kinesthesia and active touch whereby Helen Keller overcame her sensory defects. He was almost postureless and lacking in the simple postural sets which normally lie at the basis of attention and mental adjustment.

It may be argued that the fullness of A. C.'s development depended upon the intactness of his auditory and particularly his visual functions. Visual experience was probably least affected by his brain injury. His eye grounds were normal and the early internal strabismus was self-corrected. He even attained the ability to make eye movements of a reading type. It is possible that the kinesthetic data furnished by his 12 oculo-motor muscles supplied the main scaffolding for his mental equipment.

These muscles, it may be contended, were able to muster and maintain within themselves a degree of postural set. By such reasoning the motor theory of mental growth can be retained. The argument simply states a) that there is a tendency toward optimal

realization and integration of potentialities; b) this tendency caused the total mental growth complex of A. C. to organize itself about a nucleus of oculo-motor experience. It seems to us, however, that this interpretation strains both the theory and the facts.

How shall we explain the numerous propensities and strivings toward attainments for which this handicapped boy had no equivalent motor realization or even possibility of motor execution? Even at the age of six months, as already noted, he showed an unmistakable propensity to reach for objects. This propensity persisted although it never came within the scope of consummation.

In reviewing his life history one definitely gets the impression that his neurological growth did not altogether depend upon the stimulation of motor experiences. It is because the unimpaired regions of the brain realized such a full measure of their potential growth that he gave no evidence of suffering from a form of secondary amentia. This does not mean that his intellectual life was not impoverished; but it means that he retained a kind of discernment and discriminativeness which were normal in quality.

We infer therefore that the insurance factors of maturation brought about a considerable degree of neurological growth in unimpaired regions of the brain even though these regions are cut off from normal subcortical (tactile-motor) impulses. Such insurance factors enable the organism to some extent to build bricks without straw. It is difficult to think of mental organization apart from tangible (tactile-motor) components. But the new concepts of growth chemistry permit us to believe that the protein molecules of the central nervous system, in a living medium, may undergo considerable elaboration and electro-dynamic organization without the stimulus of patterned motor reactions.

With such concepts the evidences of normality in certain cases of cerebral palsy become less engimatic. There is, after all, no inner necessity why profound motor disability should create or produce an equivalent measure of mental defect.

We draw from all the foregoing the general conclusion that, even in extreme forms of neurologic disability, the patterning of behavior tends toward an optimum of order and organization. Expressed negatively, the deterioration of behavior is not commensurate with the destruction of the primary sensory and motor mechanisms.

The degree of patterned mental growth which takes place after a vascular injury to the brain at birth is not entirely determined by the motor disability itself; but by innate endowment, by the areas of the cerebral cortex unharmed, and possibly by the opportunities for the compensatory development of neuroblasts and neurones. Endowment and compensatory response may well have some interdependence; so that a potentially superior nervous system will be less affected by a lesion than one of lesser grade. For all these reasons natal brain injury results in varying degrees of intellectual and motor impairment. There may be extreme and extensive paralysis without mental deficiency. There may be slight paralysis with extreme mental deficiency. The momentum and limits of mental growth are influenced more by the psychic or symbolic systems than by the sensori-motor, whether cortical or subcortical.

Mental Growth Tends Toward an Optimum Realization.—If the sources of energy on which growth depends are not completely stopped, as they are in profound idiocy, there remains a measure of specific and general potency. This potency expresses itself in the progressive maturation of modalities and dispositions of behavior, even when normal patterns of behavior cannot be consummated. This is the almost irrepressible quality of growth. This is an insurance factor which works toward adjustment and integration even in the gravely handicapped child. Accordingly there is an optimum utilization of impaired instrumentalities and impaired impressions.

Although this principle of development applies to cases of cerebral palsy it does not in itself bake us any bread. The optimum is not always the maximum. It is easy for the victim of cerebral palsy with all its attendant circumstances to become over dependent. From the standpoint of treatment the primary problem is to appraise correctly and to release the patient's potentialities for self directed effort.

§10. Summary.

1. A first detailed study, correlating behavioral data with neuropathologic findings in a case of cerebral palsy is presented.

2. The psychological development and behavior characteristics of A. C. were investigated by repeated observations, cinema records, and a training program, until his death at the age of 14 years.

3. Necropsy showed an uncomplicated lesion of the basal ganglia, of the classic *status marmoratus* type.

4. A tabular summary lists the neuropathological and behavioral findings and brings normal and observed functions into comparison.

5. The cinema records of A. C. at 7, 10 and 13 years were subjected to frame by frame analysis to ascertain evidences of pattern in the apparently erratic movements of his double athetosis.

6. This cinemanalysis revealed temporal and spatial pattern characteristics similar to those of the spontaneous supine activity and the tonic neck reflex of normal infancy. Eleven comparable pattern phases in A. C. and a normal four weeks old infant are identified and delineated.

7. The psychological characteristics of A. C. are interpreted in relation to his autonomic, sensori-motor, intellectual and social behavior. The limitations of motor theories of mental life and of mental growth are pointed out.

8. In spite of the paucity and disfigurement of kinesthetic experience, A. C. showed remarkable integration of personality and significant approximations to normal mentality.

9. Considerable maturation takes place in unimpaired cerebral areas even when they are cut off from normal tactile motor communications.

10. The blemish of behavior patterning is not commensurate with the destruction of the primary sensory and motor mechanisms. Mental growth tends toward an optimum organization.

DISCUSSION.

DR. BRONSON CROTHERS (Boston, Mass.).—I had a particular interest in this case because I saw the boy at the beginning of this experiment in New Haven, and also one of Dr. Gesell's colleagues, Dr. Elisabeth Lord, has worked with us for many years in the Boston Children's Hospital.

There are two things that are striking, one of which is that Dr. Gesell described a neurological case without knee jerks, or any of the ordinary signs, but laid stress on the developmental importance of these tonic neck reflexes.

We have been able over a period of 15 years to observe a good many of these cases, not with Dr. Gesell's supreme skill in cinemanalysis, but with many reels of moving pictures over a number of years.

We so far have never seen one case showing tonic neck reflexes after early infancy who has ever walked. If that is true, the attempt to elicit indisputable evidence of tonic neck reflexes in disabled children is of far greater importance than it is supposed to be.

The other question, which I hope Dr. Gesell will discuss a little more, is the validity of his observations in the field that is ordinarily thought of as abstract. I do not know exactly how to describe it, but as I understand it, questions which will elicit an answer of yes-or-no are his main method of investigation, and the thing of which it reminds me is the dilemma in which the physician often finds himself, where the mother tells you that the child understands everything that is said.

I have had that experience too many times to feel that it is an easy question to answer, but certainly, in order to convince one that the child's development was at or near a normal stage, I would like to know what kind of questions Dr. Gesell was able to get satisfactory and illuminating yes-or-no answers as the child approached the age of 12 or 14, otherwise it is a little difficult to prove this case about that period, although it was abundantly proved at four and a half, five and six. But the development from then on is rather subtle, and not entirely covered by the abbreviated paper as it was read.

DR. ARNOLD GESELL.—Dr. Crothers' point is well taken. It is discussed at greater length in the original paper. We gave considerable weight to certain observations in situations which we did not ourselves plan, but in which the boy's spontaneous reactions showed discernment and insight. For example, on one occasion when he was "attending" a rural school, the teacher failed to dismiss the group at the regular time. By an increased agitation of movements he called eager attention to the fact that they were running overtime. He could read the clock. So he was made school monitor!

Undoubtedly there was real intellectual impoverishment, because of failure to command spoken and printed language, but we would stress the normal aspects in the quality and the modality of his responses. The steady maturing of his personality and emotional patterns also is significant.

PUERPERAL PSYCHOSES AND THEIR SEQUELLÆ.*

By LOUIS J. KARNOSH, M. D., AND JUSTIN M. HOPE, M. D.,
Cleveland.

In 1848 in Essex, England, at the Lent assizes, a poor woman was tried for the murder of her infant by cutting its throat. All the evidence supported the theory that the defendant suffered with an insanity which came on a few days after delivery. The attending surgeon testified and considered her to be laboring under puerperal mania. It is recorded that his evidence was most straightforward and clear, for undoubtedly he had read the masterful lecture on the subject by Conolly,[1] which had been published two years before. The Lord Chief Justice, who presided, in summing up the case, considered this opinion as very rashly formed and carelessly given. Nonetheless the jury returned a verdict of not guilty on the grounds of insanity.

The editors of *The Lancet* in the crisp fashion of the day took the learned jurist severely to task for the unjust imputations upon the professional ability of the medical witness.[2] It so happened that the judge's own father had been an eminent obstetrician who had written at great length on this very subject of puerperal mania and had particularly stressed the care which is ever to be taken "that the patients in their fits of despondency and rage be prevented from doing mischief to themselves or others." "We specially commend these latter words of his able father to the attention of the Lord Chief Justice," the editors artfully concluded, "for they are sufficient to explain all that seems unintelligible to his legal descendant."

Such sensational and personal tid-bits incidental to the trial were picked up by the lay press, even as they are now, and for a number of years the subject of puerperal mania was one of stirring interest and animated discussion in the coffee-shops and chop-houses of London.

* From the Neuropsychiatric Division of Cleveland City Hospital and the Department of Nervous and Mental Diseases, School of Medicine, Western Reserve University.

Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

As a direct result an avalanche of articles on puerperal psychosis descended upon *The Lancet*. Among these one by Webster [3] is noteworthy because it offered some interesting statements respecting the frequency of puerperal insanity. He stated that out of 1091 curable female patients at Bethlem Hospital, an eighth of the whole were puerperal cases, thereby denying the claim of William Hunter that the malady was not a common ailment in England. The same article included the details of one autopsy, the principal morbid alterations being "turgidity of the cerebral vessels and membranes, large, bloody points on cutting the cerebral substance and considerable effusion of fluid in the fifth ventricle."

Another paper emanating from the temporary excitement over the subject hinted that the new practice of chloroform inhalation during childbirth may account for a certain proportion of these mental disturbances.

These historical items are being exhumed to show that in the pre-psychobiological era mental disorders associated with childbirth were respected as a definite clinical entity. This idea persisted even though Marce [4] in 1852 was asserting that such a concept was not justified. Current psychiatry does not look upon these psychoses as a group which merits a clear nosological classification. Rather they are regarded as composite phenomena or resultants of an underlying biogenic weakness, super-imposed psychological stresses, and precipitating toxic and exhaustive factors. According to the findings of Kilpatrick and Tiebout,[5] Frumkes [6] and others, the fundamental features displayed in psychoses following childbirth are in no wise different from those of biogenic psychoses which are not associated with the puerperium, as far as symptomatology and prognosis are concerned.

Two-hundred and thirty-one cases were selected from such sources as the receiving psychopathic hospital, private sanitaria, two maternity hospitals and all general hospitals in the registration area about a large metropolitan center. The incidence of all psychoses associated with child-bearing was first plotted against the curve of the total number of births in the same registration area, to determine whether or not such psychoses were a biologic or organic constancy (Fig. 1). From the findings here, it is obvious that the ratio is a variable one, the chances of a woman's becoming

psychotic from childbirth varying from 1 in 458 to 1 in 1370. The same wide variability is found on referring to various obstetrical texts, such as that of Williams,[7] who notes a ratio of 1:616 and 1:1100, as compiled respectively by Berkley and Jones.

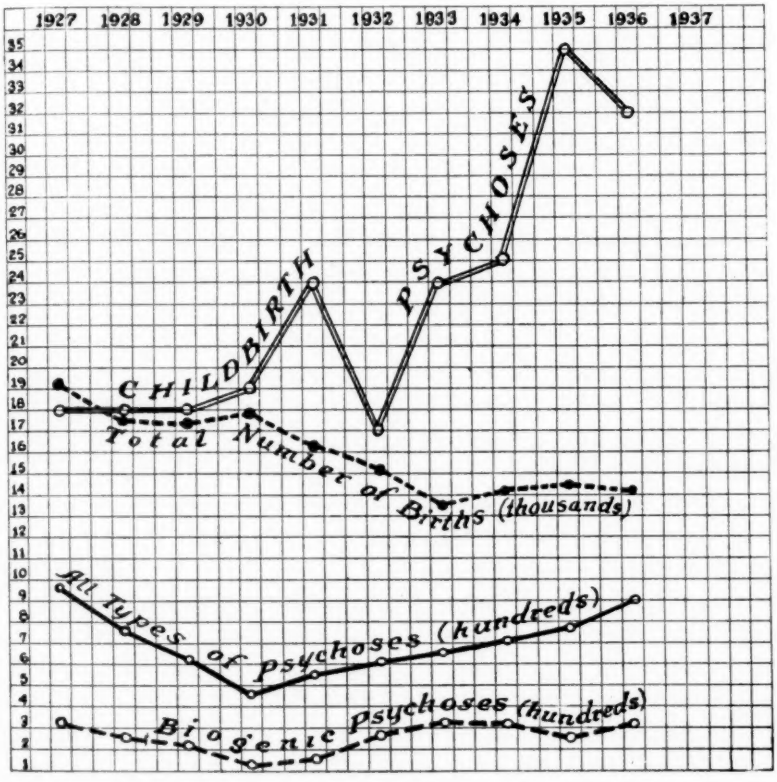

FIG. 1.—The incidence of childbirth psychoses compared with the total number of births in the same registration area over a period of ten years. These psychoses are further compared to the total turn over of new psychoses in the same community, and to the biogenic psychoses over the same admission period. There appears to be no fixed constancy of puerperal psychoses as compared to the birth rate or to the total psychotic population.

This rate of frequency of childbirth psychoses was next plotted against the total turnover of all types of psychoses occurring in the same decade, and also against the curve of the so-called biogenic psychoses. Again the incidence of psychoses associated with

childbirth failed to keep pace with these constituents, for no strict parallel was detected.

What speculation can therefore be allowed to explain this atypical behavior? It can be seen that the number of cases shows a general increase beginning with the year 1931. It becomes necessary to consider extraneous and situational causes, such as the economic stresses of the present time and their immediate and remote effects upon personal and domestic harmony. Such factors have been repeatedly emphasized, particularly in the reports of Saunders [8] and Zilboorg.[9]

This theory is by no means a new one, for ninety years ago Conolly [1] stated that " epochs of national excitement, which exercise an influence on all forms of insanity have been found to make the occurrence of it in the puerperal state more frequent." Esquirol [10] records that in the years 1814 and 1815—years including the invasion of France, the abdication of Napoleon, his return from Elba and his final defeat—the cases of this malady were more frequent than usual in France. That psychoses incidental to childbirth are heavily influenced by situational and psychological tensions can be further confirmed by studying the content of these disturbances where one will readily encounter the familiar elements of hysteria, psychasthenia, anxiety states and other reactive phenomena.

Because there is a wealth of mental phenomena encountered in pregnancy, many observers are of the opinion that the term " puerperal insanity " is too narrow a one and should be discontinued. They believe that the physical and mental ordeals of the pregnancy period are the accumulative forces which are largely responsible for the ensuing psychosis. The data obtained from the group presented does not support this contention. While it is true that pregnancy is often marked by peculiar whims, caprices and sporadic irritability, by and large this period was frequently recalled by the patients themselves and by relatives as one of remarkable complacence. In the vast majority of cases in this series the mental outbreak appeared as a distressing and unexpected complication only after pregnancy was terminated. It is a common observation on the part of obstetricians and family physicians that during the period of pregnancy neurotic women often become more placid,

functional tremors and choreas temporarily disappear, epileptic seizures and periodic headaches are absent and psychoneurotic features are in abeyance. Zilboorg,[11] who elucidated the symbolic material as it is found in the post-partum schizophrenias, states that pregnant women pass through an " orgy of libidinous joy," as they enter the stage of parturition. Zilboorg [9] also reports that only 2 to 23 per cent of all psychoses associated with childbirth occur during the gestation period. This torpor of temperament naturally exists only if pregnancy is not complicated by toxemia, eclampsia, deficiency disease, extreme varicosity or some other physical distress. Such conditions are naturally excluded from this survey.

Of the entire group herein presented, only two patients displayed a frank psychosis during pregnancy which could not be interpreted clearly as an expression of somatic disease. One was an older primipara who became pregnant as an accidental feature of an already established manic phase, promptly entered a depression on being apprized of her condition and who continued in this state through labor, puerperium and the entire lactation period. She did not recover until a year after her delivery. The second patient was a case of frequently recurring mania who maintained this condition throughout pregnancy, delivered spontaneously, and continued in wild psychomotor exultation for many months after childbirth. In neither case did the events associated with labor, involution of the uterus and lactation make any impress upon the already established psychosis.

It appears, therefore, that no matter how threatening or potent may be the anxieties and eccentricities of the pregnancy period, a true psychosis rarely supervenes before delivery occurs, before involution of the reproductive organs enters into the picture and the process of lactation begins.

The stormiest psychoses associated with child-bearing develop in the period immediately after delivery. Strictly speaking, the onset occurs not at the beginning of the puerperium but coincides more accurately with the appearance of lactation. With the exception of two cases in this entire series—and these women were chronic alcoholics—no patient displayed a frank psychosis until the third day or thereafter. There is, therefore, a definite latent

or incubation period, frequently the mental symptoms appearing on the same day as the onset of lactation.

By far the most common denominator in these acute puerperal psychoses is a delirium; the more abrupt the onset the more profound is the clouding of the sensorium (Fig. 2). In 24 per cent of the patients in this study, this was the dominant component, the peak of its incidence occurring about the sixth post-partum day. This is an average incubation period of considerably shorter dura-

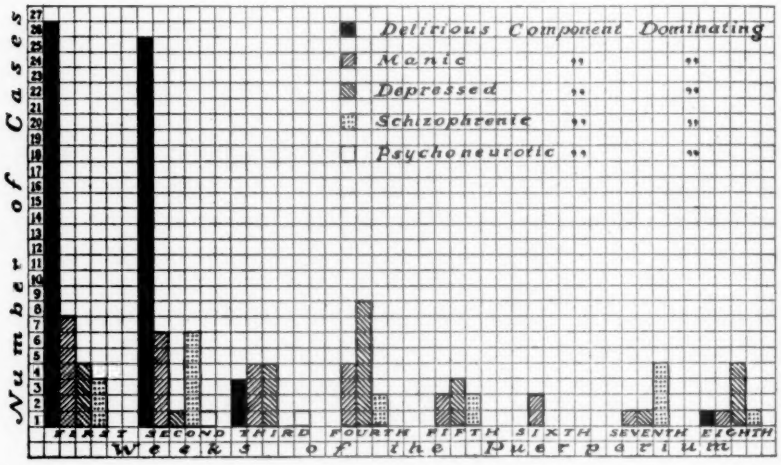

FIG. 2.—The distribution of puerperal psychoses in reference to incubation period and to quality of psychoses. Most of the episodes of the first four weeks contained a delirious component, but only those which manifested this element, to the exclusion of other psychotic features, are indicated as being of the delirious type.

tion than that reported by Strecker and Ebaugh [12] which was 22 days for the toxic-delirious types.

The delirium was of varying intensity and was often intermingled with other psychotic elements which were brought into being almost at the same time. It should be stated that most of the acute manias, many of the schizophrenic outbursts and a few of the depressed types contained a delirious element in the earlier phases but are not so recorded. Not only did Strecker and Ebaugh report 34 per cent as being of the purely toxic-delirious type, but over 77 per cent of their manic group were qualified as having a clouded sensorium. Panic, confusion, sudden aversion to and dis-

trust of relatives, misidentification, hallucinosis, sing-song jargon and disintegration of normal affect together with a rapid pulse, tremor, quick dehydration and a fever ranging from 99° to 102° were the most constant features and are familiar to every observer.

This acute picture was such a clinical melange that it was rarely possible to make any accurate predictions as to the outcome. Only when the delirious features subsided did the concomitant biogenic elements emerge clearly enough to be recognized, if they were present at all.

Eventualities which appeared when the element of delirium abated can be briefly presented as follows:

(a) Delirium followed by quick recovery or death.

(b) Delirium followed by a manic phase and recovery.

(c) Delirium followed by a depressed phase, with recovery or a chronic depression.

(d) Delirium followed by a schizophrenic psychosis with only an occasional recovery.

That true delirium may exist in these patients without specific infection or a clearly defined toxic agent was confirmed in two necropsy studies. In both of these cases typical "wet brains" were found, one brain weighing 1400 grams and the other 1225 grams, these findings being associated with the familiar picture of acute cloudy swelling in all the parenchymatous organs.

Microscopic section studies on the brain of one of these cases revealed nothing beyond an increase in the size of the subpial spaces, as indicative of œdema, and an abnormally thin ependymal lining. Sections through the second brain revealed an increased number of micro- and macro-glial cells. The glial tissue under the meninges was frayed and œdematous, and the larger nerve cells were œdematous. Sections through the medulla showed severe granularity, loss of staining property and in many instances loss of nuclei of the larger motor cells. In addition the glial tissue of the medulla was frayed and œdematous. Sections through the cerebellum revealed no significant abnormality. While some of these interpretations are open to question and the changes may be within the realm of artefact, the excessive glial proliferation is a significant pathologic finding.

What is the delirium-producing factor in this period? Obviously it is one feature of psychoses associated with child-bearing where

toxic or endogenous processes must be considered, and which cannot be explained away on the basis of psychological conflict or even on constitutional deficiency. So far no specific mechanism can be demonstrated.

Endocrine disturbances have been suggested as a cause, although Saunders [8] and other workers found no evidence to sustain this belief.

Hormone assays, such as are available at the present time, are extremely difficult to carry out on patients who are suffering with acute mental disturbance. In this series it was possible to obtain prolan estimations on 10 women in the first 10 days of the puerperium and quantitative estrin assays on six. In every instance the results were low, readings which do not, however, differ from those of normal, non-psychotic women in the same phase of the puerperium. It should be recalled that the action of the lactogenic hormone is inhibited in part during pregnancy by high estrin content in the blood. It can act only after the mammary tissue has been prepared by the estrin and the latter has been reduced to a minimum. The action of prolactin is solely to initiate and excite milk secretion.

Acting upon the suggestion of Anselmino and Hoffmann,[13] the use of anti-galactogogue principals such as antuitrin-S and theelin have been given in 20 cases to terminate lactation. This method has been no less successful than the administration of salines and breast compression in inducing rapid delactation, but it is doubtful whether either method had any direct influence on abating the delirium.

Apparently the delirium-producing factor initiates its effects before or just at the beginning of lactation. In its intensity and sudden onset puerperal delirium resembles the thyroid crisis which follows upon an operation for toxic goiter, and which, according to Dinsmore and Crile,[14] may be due to acute failure of the glycogen stores in the liver.

Because the toxic or delirium-inducing factor is so sharply limited to a definite portion of the puerperium, because its time relationship to lactation is so suggestive, because it cuts across all personality types either to cause sudden death, to disappear, or to precipitate into active state certain biogenic mental distortions,

one should keep an open mind to the possibility of a specific endocrine or other endogenous crisis.

Smith and Smith [15] have already demonstrated that a disturbance in the estrin-prolan ratio in late pregnancy may be a sign of impending toxemia. The complete mechanism by which the lactogenic hormone is released, the reason for its lack of action during pregnancy, the rôle of the liver, pancreas and parathyroids in milk production and other topics in lactation are, as yet, not definitely understood. As long as this state of our knowledge of the subject obtains, it is untimely to state that the endocrines are not a factor in the production of post-partum mental disease.

It is no cheap empiricism or shallow rationalization which is frequently heard by psychiatrists that many women "have not been the same since the birth of the last child." The many mild post-puerperal regressions, insidious disintegrations of personality and chronic psychoneurotic distortions which occur after several puerperal episodes can never be accurately evaluated, for rarely do they come to the attention of psychiatrists, or the longitudinal story is not accurately revealed. The post-puerperal destinies of those who have had a major puerperal upset can be more clearly presented.

Many psychoses do not appear until after the puerperal period has passed. These delayed or more insidious disorders are popularly called lactation psychoses. In this series these belated upsets were chiefly schizophrenic, melancholic and psychoneurotic states and showed every evidence that constitutional and situational causes were dominant. The delirious component was notably lacking.

Life curves of a few types of puerperal psychosis, particularly the manic-depressive, the delirious, who are ordinarily regarded as recoverable cases, and a few out of the schizophrenic group, illustrate the post-puerperal and more remote events which ensued once a delirious puerperal psychosis had been experienced.

The Manic Type.—The post-puerperal record of 11 cases of puerperal mania are shown in Fig. 3. Most of these individuals can be called syntonic as to pre-psychotic temperament, a large number being Jewish. The acute puerperal attack was almost always of a delirious-manic variety. The subsequent history revealed a definite exaggeration of the cyclothymic trend with frequent episodes of manic-depressive psychosis, even though no later preg-

nancies occurred. Many of these recurring attacks were severe enough to justify re-admission to a psychiatric hospital. Apparently the toxic-manic illness in the puerperium induced an organic change which thereafter expressed itself in the form of a more exaggerated cyclothymic disposition.

The Simple Delirious Type.—Psychobiologic studies revealed that in this group hereditary taint was minimal and the pre-psychotic personality was interpreted as being the least unstable. The same

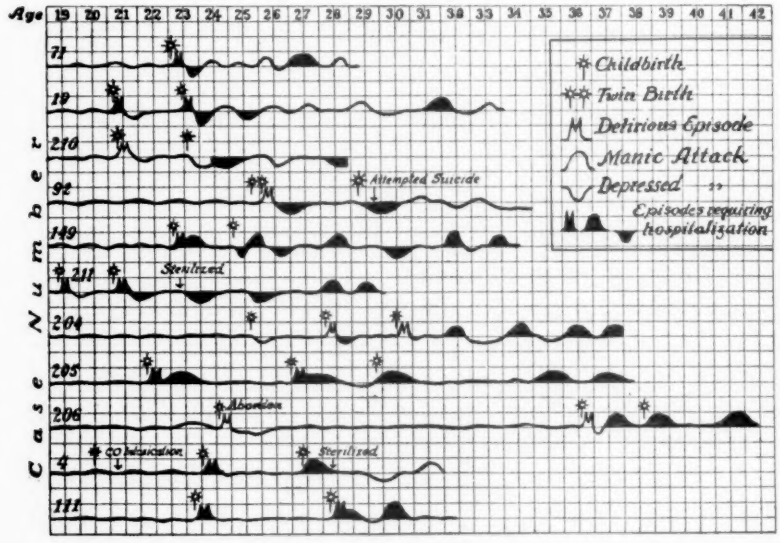

FIG. 3.—A chronological scheme illustrating the further course of events which occurred in eleven women where primary psychosis was a puerperal delirious mania. It appears that these acute delirious psychoses produced in these patients a pathological cyclothymia marked by frequent manic depressive episodes. In none of them was there demonstrated a major psychosis prior to the puerperal delirium.

impression of these purely delirious types was expressed by Strecker and Ebaugh.[12] Three of these died in the delirious state, necropsies for two of which were described above, while the rest recovered after a short convalescent period. Five of these were under scrutiny over a period long enough to make possible a record of the subsequent mental course (Fig. 4A). Not only does this group show a tendency to duplicate the delirium after subsequent pregnancies, but the same reaction may follow on the heels

of an acute infection or slight head trauma. Hence one can theorize that these individuals have a ready diathesis to benign delirium and we can term them " deliroid " in the same sense as we use the term schizoid or cycloid.

The Schizophrenic Types.—The most protracted, most severe and utterly tragic events in the wake of an acute puerperal psychosis occur in the so-called schizophrenic group, particularly when the ancestral record is positive for mental disease. Seventy-one per

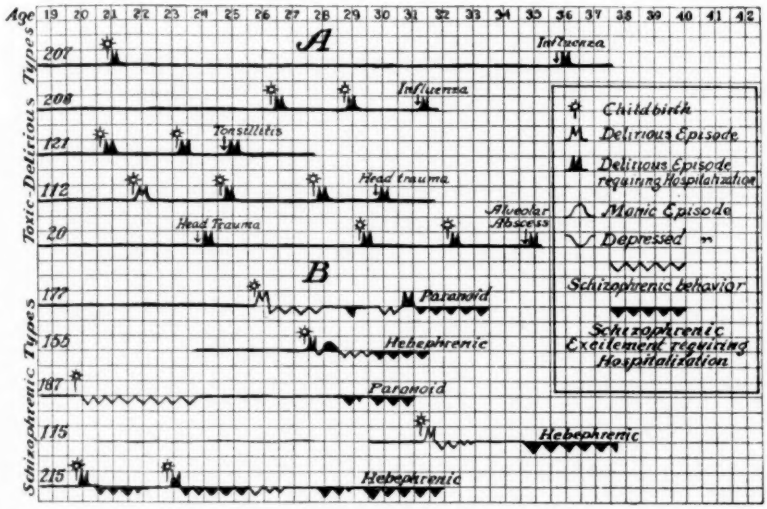

FIG. 4A.—A chronological scheme demonstrating the diathesis to pure delirium in five patients whose life curves are not modified by any other biogenic disturbance. In these patients there is no evidence of serious distortion of pre-psychotic temperament, and recovery is the rule.

FIG. 4B.—A sampling of the longitudinal course of the schizophrenic type of puerperal psychoses. Following an initial puerperal delirium there emerges the erratic and irregular behavior pattern which usually culminates in regression or chronic paranoid deterioration.

cent of these failed to rally from the original upheaval and continued to show the disjointed behavior characteristic of dementia præcox. Prominent in this degenerative picture was found a trend toward regression into infantile and immature mental and emotional behavior, which is characteristic of hebephrenia. In this group the greater percentage obviously remained under institutional management (Fig. 4B). Those showing the milder hebe-

phrenic residues were intermittently allowed their freedom. Exacerbations in the form of catatonic excitement, silly unpredictable behavior, inability to assume the simplest domestic responsibilities, were reasons frequently given for reincarceration. In this group occurred two infanticides and one homicide.

SUMMARY.

1. The assembling of statistical data on psychoses associated with childbirth appears to show that their frequency is heavily influenced by situational and social factors. These psychoses do not appear to be of fixed constancy in relation to the total number of births in the community or to the biogenic psychoses in the population.

2. The only consistent or characteristic element in true postpartum psychoses is delirium, which appears in varying intensity. No specific endogenous or exogenous factor is revealed, although complex endocrine imbalance cannot be definitely eliminated at this time.

3. In women of cyclothymic disposition a delirious mania following childbirth may lead to an increased frequency and an easier tendency to manic-depressive cycling, even though subsequent pregnancies do not occur.

4. The purely delirious types which recover rapidly are individuals who are generally of stable pre-psychotic matrix. However, subsequent attacks of delirium occur in some, which indicate a low threshold to this type of psychosis and to no other.

5. The most persistent and tragic residues are found in those women whose personality structure is in the schizothymic direction and whose inheritance is tainted. Here the outstanding trend is to hebephrenic regression.

DISCUSSION.

DR. JOHN P. POWERS (Boston, Mass.).—I am not in accord with some of the statements of Drs. Karnosh and Hope. I do not believe there is a true puerperal psychosis. I believe psychoses following delivery are ordinary psychoses which would be found with or without childbirth.

Furthermore, I consider the delirium to be the same as that found in any condition. I feel the necessity for further proof of a connecting factor between the delivery and the psychosis before I accept the term, "puerperal psychosis."

In this paper it was stated that the term should be discontinued, and with this suggestion I agree.

In the practice of medicine we must be careful to refrain from arguing that because there was a delivery, the resulting psychosis is due entirely to it. I am inclined to think that the resulting psychosis is due to a break in a manic-depressive, or paranoid temperament, due to some other factor than the pregnancy itself.

If it is possible to make a diagnosis of any one of these conditions as a post-puerperal case, without knowledge of or information proving that there has been a childbirth in a particular patient, anyone making the diagnosis of a post-puerperal psychosis is bound to be on the defensive.

In 3250 autopsies done by the Department of Mental Diseases, only three were listed as post-puerperal. Probably others are lost in the toxic-infectious group or are classed as dementia præcox. In the cases so diag-

nosed these pathological conditions were bound to explain the psychosis: In the first, multiple cardiac thrombi, embolism, contributory edema and hydrothorax. Final diagnosis: Psychosis with other somatic disease.

Second: Acute and chronic endocarditis, contributory cerebral thrombosis.

Third: Pulmonary thrombosis, contributory infarct.

DR. ERWIN WEXBERG (New Orleans, La.).—May I ask the doctor whether the basal metabolic rate has been determined in these cases?

DR. KARNOSH.—No, just in a few cases where we believed it was indicated. No basal metabolism is possible in excited cases.

DEVELOPMENT OF FAMILY CARE IN NEW YORK STATE.*

By HIRAM G. HUBBELL,
Clinical Director, Newark State School, Newark, N. Y.

Family care of mental defectives has been in operation at the Newark State School since 1931, a period of six years.

A system of extra-mural care has been in operation for a number of years, but only for the higher grade of patients. We have colony houses where patients go for training in domestic work for the girls, and farm work for the boys. They go out to work by the day, and return at night to the custody of the matron in charge of the colony. After sufficient training, they are placed on parole to the custody of their employers, but still under the supervision of the institution. Another group have returned to their families or communities upon parole.

This left a large number of patients, who could never be self-supporting, were not trainable, or because of physical defect, would never be able to support themselves. A great many of these require only a moderate amount of supervision, but have been gradually filling up the institution, and restricting the number who could be admitted for intensive training.

We have been very much impressed by the type of family care given abroad to psychiatric cases who need only a moderate amount of supervision, especially at the colony at Gheel; and we have felt for a long time that a great many of our cases could be placed to advantage under this type of care. Also, we have many children in the school sent to us through no fault of their own, but because of broken homes, insufficient or careless supervision, etc. If they were to remain in the school, they would gradually become institutionalized, and perhaps a great many of them would remain for the remainder of their lives. We have felt that a great many of them should not be deprived of an opportunity to grow up in the community outside of an institution, and in August, 1931, we began

*Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

placing a few children in boarding homes in nearby villages where they could attend school and mingle with normal children. By January, 1933, six children had been placed satisfactorily.

At this time, we began to think of placing adult patients, who would never be self-supporting, in families where they would be well taken care of, and given a slight amount of supervision, and live in a more normal manner. Realizing that if we were to carry out this idea in an extended manner, it would be essential that they be placed, generally, in a small community where it would be possible for the physicians and social workers to supervise them closely, we decided upon the Village of Walworth, a small town of about 300, located 16 miles from our institution. This village is located away from the main thoroughfare, four miles from a railroad, the residents being very high type citizens. We, therefore, contacted the local physician, who recommended several homes, and in the first home investigated we were very fortunate in finding a boarding mother who had a fairly large home and who, at once, became very much interested in the project. She was also a practical nurse. On January 9, 1933, two women, one 49, and the other 50 years of age were placed in this home, and at the same time two others were placed in a nearby home. This woman, because of her knowledge of the residents and suitable homes, was a great help to us in placing additional patients. The numbers increased, and we began to find it very essential to have a community center where patients could assemble for social gatherings, for interviews and inspection, and where clothing, medical supplies etc., could be left for distribution. We decided upon the home of the first boarding mother, who was then placed on a regular attendant's salary, and who, in return, agreed to provide a community center room in her home where patients could be left if their boarding mothers wished to go away for a day, or where they could be brought in case of minor illness. Two beds were provided in this home. Our occupational therapist attends at this community center at frequent intervals to provide various forms of occupation, recreation and social gatherings for the patients. The boarding mother also looks after the general health and welfare, and reports anything that needs the particular attention of the school. She cuts their hair, trims their nails, etc., and acts as general over-

seer, keeping in close contact with our social worker, who has charge of this group under the clinical director.

The project has grown to such an extent that it requires the undivided time and attention of one social worker, who investigates all homes before the patient is sent out, and recommends to the physicians suitable cases for family care.

As a rule, we place only two individuals in each home, as we believe in this way they receive more individual attention from their boarding mothers, and are made members of the family. In cases with a physical disorder, such as blindness, or a crippled condition, we have placed four in a family in order that two healthy patients may help to look after the two others, helping them in dressing and getting about from place to place.

At first the residents of the town were rather disinclined to receive patients in their community, as they felt that the patients were peculiar or insane, and would be a menace to the town; but as more and more have been placed and they go about the streets causing no trouble, we have been having more applications for homes than we can fill. All the patients do not reside within the village limits but many are placed on nearby farms where they are able to get to the community center from time to time. In general, the people of the village have shown a very sympathetic attitude toward them, and have given them many privileges. They attend church, various social gatherings, and are often provided with tickets to entertainments in the village.

We have divided this project into three groups as follows: family care—community; family care—school; family care—individual. In our community group at the present time, we have 88 patients whose average age on admission to the school was 27 years with an average length of residence in the institution of about 20 years. The average intelligence quotient of these cases is 47.5. We find that women are much more adaptable to the community home than men, although we have several boys in our school group.

The next group, family care—school, is made up entirely of children of school age. From the first, we have felt that it would not be wise to place children in our community group of older patients, but decided to place them wherever a good home could be obtained, and where they would have adequate school facilities.

We are intensely interested in this group for we feel that a great deal can be done to rehabilitate them, and avoid making them life-long institutional cases.

At the present time, we have placed 28 in 18 homes in surrounding villages and school districts. We have found that the most satisfactory age is from 6 to 12, although we have placed a few at the age of 14. We prefer to start them as young as possible. Their intelligence quotients range from 47 to 86 with an average of 62. Twenty attend grade school, 6 district school, 1 parochial school, and 1 is too young to enter school until this fall.

Previous to coming to the school, a number of the children had been tried in various boarding homes, and shifted about from place to place because they did not make progress in school, or the boarding mother had other normal children and did not wish to be bothered with them. However, in almost every case, they have adjusted well in the homes that we have provided, and for the most part are doing surprisingly good work in school.

To illustrate the progress made in this type of care, I should like to quote from the records of a few cases.

C. V., female, age 12 upon admission to the institution in 1930, mental age 7 years 2 months, I. Q. 59, was placed in boarding home in October, 1931, where she made excellent progress in school, took a great deal of pride in her work, both at home and in school. She was started in the third grade, was soon promoted to the fourth, and was able to do all the fifth grade work, except arithmetic. She showed a great deal of interest in helping to care for other children, and thought she would like to be a child's nurse. During the summer of 1935, we were able to provide her a position in a private institution for children where she received instruction in their care. At this time, she had passed to the sixth grade with good marks. Following this, she was placed in another home where she was promoted to the seventh grade in another school, and the following month was advanced to the eighth grade. Her boarding mother taught her housekeeping and cooking. Now, at the age of 19, we are planning to get work for her in an orphanage or hospital, and she is making her plans to enter a school of practical nursing when she reaches 21.

E. V., female, admitted October 7, 1931, at the age of 12, I. Q. 63, was placed in a boarding home October 5, 1933, with a history of temper tantrums upon the slightest provocation, screaming and yelling and abusing other children by slapping them and pulling their hair; had been in various boarding homes from the time of her birth until no one would have her, and she was placed in a home for children. After going to our boarding home, she was placed in the fifth grade in school. At first, she was impudent, careless in her habits and cried easily. At the present time, at the age of 18, she is in the

eighth grade in school with reports as follows: history 83, spelling 95, English 76, arithmetic 64, civics 64, reading 91, designing 80, average 77.1. There is a marked improvement in her personality. She no longer shows temper tantrums, is pleasant and agreeable, and has been made president of her class. Wants to be a nurse, and some arrangement will be made for her to care for children or take a course in practical nursing.

J. W., female, admitted July 24, 1933, at the age of 12 years 5 months, mental age 9 years 7 months, I. Q. 76. She had been sent because the father was immoral with the children, and the home had been broken up. She had been placed in several boarding homes previous to admission where she was no real problem, except that she was lazy, slovenly and disobedient. She had reached the fourth grade in school. We placed her in boarding home in September, 1933. At first she was rather irritable and quarrelsome but by December of the same year, she was noted as getting on splendidly in school, and was an honor student. Her conduct improved. She has become more ambitious, and has now started in the eighth grade where her last marks were: history 80, arithmetic 85, spelling 75, English 60, reading 60, civics 73, designing 80. She wants to go through high school.

Another child, admitted in 1931 at the age of 12 with an I. Q. of 49 was placed in a boarding home in October, 1933. While she has been unable to progress beyond the opportunity class, she has a very nice personality, is well liked, has sung in the church choir for a long time, and as she is now 18 years of age, she has been taken out of school, and placed in another boarding home where she earns her board and 50 cents per week while being trained in domestic work.

One small child does not like to talk to the social worker upon her visits, as she fears she may be returned to her own home.

Eleven of our girls have joined the Girl Scouts. All attend church and Sunday school.

In one home, we tried placing a small boy and girl, and this has worked out very well.

We were able to place a little colored boy in a colored home where he goes to school with the boarding mother's boy.

The children are in the following grades at school:

1 too young to attend school.
2 in kindergarten.
4 in special class.
4 in first grade.
2 in second grade.
6 in third grade.
2 in fourth grade.
3 in fifth grade.
1 in seventh grade.
3 in eighth grade, the latter taking some first year high school subjects.

We have never made any attempt to influence the placement of children in school, but if requested, we furnish the I. Q.

Taking up our third group in family care—that of individual cases, we found that several of our patients who had formerly sat about the institution with no interests whatever, and making no effort to do anything for themselves, had become more alert after going to boarding homes, and were able to do enough work in the families to pay for their board and lodging. These were removed from the community and placed in families who wanted a little help but were unable to pay standard wages. These cases receive excellent care and supervision, and get 50 cents or more for spending money. One case was advanced by her boarding mother to $2 per week. These, of course, are no longer any expense to the state. Up to January 1, 1937, we have placed a total of 202 cases, 80 having been returned for various reasons, leaving 122. Eighteen were returned during the year of 1936 for the following reasons: 8 were ill, 7 unadjusted, 1 paroled to relatives, 1 discharged, and 1 for employment.

We now come to the more practical or economic side of the question. From a sociological point of view, there is no question that these patients are happier in living a more normal life, and the children are gaining in normal contacts, something which they would never get in an institution.

In the beginning it was extremely hard to get money for this project, as it was something new and the legislature had approved no funds for it. However, we began by paying $4 each for our community cases, and $6 for children. This money we were able to obtain chiefly from our colony funds. During the year beginning July 1, 1935, the legislature appropriated $20,000 for the hospitals and schools in the State of New York under the Department of Mental Hygiene, restricted to a payment of $4 per week per inmate in family care. We have never been able to board children for less than $6, for the reason that they require more care, and are chiefly located in the larger villages where the expenses are higher, so that we were obliged to make up the extra $2 from our colony funds.

We then contacted the various county welfare departments, who had sent children to us, requesting them to pay the extra $2 which the state did not provide, and pointing out to them that these

children were able to get along outside the institution, and that if they were willing to help out to this extent, we would continue the children in our family care, or otherwise return them to their counties. We received a very encouraging response to this, and many counties are now making up the difference between what the state allows, and what is required to board the child.

Our allotted money was used up at once, and the legislature has now allotted an additional $40,000 for this school, and $30,000 to the other institutions under the Department of Mental Hygiene beginning in July of this year, and will allow payments on an adjusted scale, so that we will not be held entirely to the weekly $4 rate.

As a result of the appropriation of funds by the state, the family care of patients has been started in most of the psychiatric hospitals of the state, as well as schools under the Department of Mental Hygiene. By September 1, 1936, 283 psychiatric cases had been placed from the various state hospitals, while 426 had been placed from the state schools for mental defectives.

Quoting from Dr. Vaux' report in "Family Care of Mental Patients" by Dr. Pollock; "The combined weekly per capita cost of the two groups is $5.21. If we add the third group, individual, which is just as directly a part and product of our family care movement, we have $4.82. Combining only the last two groups gives us the figures for adults as $4.17. Thus, all the figures are below the per capita for the institution—$5.95."

This shows quite conclusively that from a financial point of view, it is cheaper to care for these cases outside than in the institutions.

DISCUSSION.

Miss Hester B. Crutcher (Social Service Department, N. Y. State Department of Mental Hygiene).—Dr. Hubbell gave an interesting picture of placing patients, as carried on at the Newark State School, but as his paper is on placing patients in family care by the New York State Department of Mental Hygiene, I shall supplement his paper to a brief extent.

April 1, 1937, 311 patients had been placed in family care from 13 different state hospitals; the state hospitals around the metropolitan area of Greater New York have not participated in this family care for the reason that there is no rural community in which to place patients. 167 patients had been placed out by 4 different state schools. Incidentally 105 of these patients were from Newark, so you realize the important part Newark has played in the development of the family care.

In the state hospitals home care is used in three different ways. I am not giving them in the way which is the most important. First, as a therapeutic measure; some of the hospitals have placed patients out in the hope that they will improve enough to be placed on parole or pending parole plans. This is perhaps where there is an antagonistic family relationship or where an adolescent couldn't possibly go back to the family because of dependency or something of that sort. The patients have gratified the hope of the hospital authorities by improving to an extent in this therapeutic family care.

Then there is one hospital that has placed out patients who worked well in the hospital but who required such an amount of supervision that it was felt they couldn't be placed on parole. So they were placed on what was called working family care. They supported themselves, but it was regarded as family care because they had to have the close supervision that the patients in family care had.

The third, and by far the largest group, are the custodial cases that have been placed out. They are patients who are not dangerous to others; they are not in need of special medical treatment that is not obtainable in a home, and they are not too disturbing factors in that home.

As Dr. Hubbell has said with the defectives, so with the mentally ill, the patients are placed out chiefly in rural communities, frequently around small towns where it is hoped that a center can be developed, somewhat similar to the one at Walworth. The patients have entered into the simple life of the community, their recreation being chiefly the family life, the church and shopping. Incidentally, our patients have been given 25 cents a week spending money, some of them only 15 cents a week. One woman who had been in the hospital 35 years, saved up her 15 cents a week for two weeks to buy herself a pair of silk stockings which we thought was indicative at least of a better community adjustment.

In the first 15 months that we have tried this (and incidentally the placing out of patients in family care in the state hospitals began July 1, 1935), 466 patients were placed out; 156 had been returned to the hospitals, 49 replaced; 35 had gone on parole and 3 had been discharged. If you compare these figures with the figures of child placing agencies, I think you will find that there is not a particularly high turnover of patients. The reasons for the return have been that the patient became physically ill or the home seemed unsatisfactory for various reasons, and failure to adjust.

As Dr. Hubbell said, we pay $4 a week, which has not enabled us to develop that rapidly, because even in rural New York it is hard to find a sufficient number of satisfactory homes at $4 a week. July 1 of this year, we will be able to raise it to $6 a week, and we hope that it will develop more rapidly than in the past.

It is interesting to see the effect this seems to have on patients. You put out a patient who scarcely talks at all and just sort of sits and has to be led to the table and helped to do this and that, and six months later you call at that home and the patient will carry on a conversation with you. Last summer I visited a patient and they thought it was quite remarkable because she pulled the rug over on the porch for me to sit on. I was out a month ago to

see the patient and she chatted with me, not a rapid fire conversation, but she talked in an amiable, social way.

Dr. Hubbell spoke of placing children in family care. The Department of Mental Hygiene does not regard itself as a child placing agency, but we had rather an anomalous situation when we had the tendency to place children in foster homes and discontinue large orphanages, the children who were dull or defective were hastily shunted into an institution, so we had quite a number of children coming into the institutions who perhaps wouldn't profit particularly by the training in an institution. We wanted to show to the county welfare officers, to the county commissioners or the county child welfare board that these children were amenable to foster home placement, just as the normal child was, and we regard that more or less as a demonstration to the various communities of what can be done with the defective child.

Another point that Dr. Hubbell brought up was that the men didn't seem to adjust so well in home care. That is quite the opposite in the state hospitals. The men patients from the state hospital adjust very well indeed, in our experience. Often people express a preference for men.

Newark has only been a co-educational institution for the last two or three years, and perhaps the men haven't been there long enough to learn to accept authority and be as amenable as the girls or the older women who are placed in family care. I think that would be an interesting thing for Dr. Hubbell to develop.

In discussing the cases which Dr. Hubbell has presented, one gets the impression that there is a great deal of pressure put on these children for academic achievement. In visiting these homes, as I have—one does not feel that that pressure is placed on the children, but an attempt is made to find the thing in which they can be successful and let them find success in that and develop along that line.

I wish that Dr. Hubbell had had further time to interpret his cases so they wouldn't sound quite so much as though a miracle had occurred. An excellent job has been done. The patients, to quote other people who visited them, seem to get brighter in family care. By that we do not mean that they develop a genius of an Einstein, but they do become more individualized and more alert and more responsive. It seems to me that regardless of the financial saving which we hope placing the custodial type of patient will be to the state, there is something far more valuable, that is the conservation of human values.

MENTAL REACTIONS AND THEIR MANAGEMENT IN PATIENTS WITH CARDIAC DISEASE.*

By P. H. DREWRY, JR., M. D., AND JAMES H. WALL, M. D.,
White Plains, N. Y.

In recent years the attention of many writers has been directed toward the psychiatric aspects of the care of patients whose chief complaints have been related to somatic diseases, and this has been particularly noticeable in relation to diseases of the cardio-vascular system. The significance of the part played by anxiety in aggravating and prolonging the incapacity of the individual, and the remedial effects of psychiatric treatment have been pointed out. The value of such contributions is apparent, and it is not the purpose of this paper to discuss the subject from this viewpoint. It is planned instead to speak of the more severe mental reactions associated with cardiac disease, that is, the phenomenon frequently referred to as "cardiac delirium." Some of the literature is to be reviewed, and a study of ten patients whose mental illnesses associated with cardiac disease brought them to a psychiatric hospital for treatment will be presented. It is hoped that some contribution will be made to a better understanding of such patients, and in turn, to their better management.

The delirium associated with cardiac disease has been recognized for many years, and almost any comprehensive textbook in either medicine or psychiatry mentions it. Thomas Watson, in lectures given in 1836, referred not only to the apprehension of the cardiac, but said: "There is a propensity to dreaming, and especially to distressful and frightening dreams . . . . and sudden starting from sleep in horror and alarm." [1] Many other writers of the nineteenth century referred to these reactions,[2, 3, 4] one of them being Austin Flint, who said: "These symptoms are apt to mask the cardiac disease, and lead the practitioner to suspect disease of the brain." [4] The incidence has been variously estimated, some authors saying that it is rare,[9, 15] and others estimating that some symptoms

* Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

of a delirious nature are present in about 10 per cent of all cardiac patients in whom the disease is sufficiently advanced to require hospitalization.[14] Our own experience inclines us to believe that the latter figure is more accurate.

Many theories have been advanced in explanation of the mental symptoms in such cases. Watson felt that the difficulty was due to a disturbance of circulation in the brain,[1] and this view has been supported by some of the more recent writers. Curtin in 1905,[5] Auban and Beurnier in 1909,[6] and Riesman[7] in 1921, are among those who have held this view. Curtin felt that the disturbance of cerebral circulation might be manifested as an arterial, venous or capillary congestion, or as a cerebral anemia.[5] Henry Head, in a comprehensive paper written in 1901, said: "A disturbed activity of the heart may alter the circulation to the brain or may change the character of the blood with which it is supplied. The delirium that accompanies a failing heart or pronounced vascular degeneration may be instanced as an example of a mental change dependent directly on altered vascular conditions."[10] Another theory is that cerebral arteriosclerosis may have a great deal to do with the appearance of mental symptoms.[8] The majority of the writers on the subject have commented upon the fact that most of the patients are over 40 years of age; and even where the sclerosis is not demonstrable, it has been suggested that there is a beginning process of senescence.[9] Other causes that have been suggested are "drugs and poisons,"[7, 8] carbon dioxide poisoning, faulty metabolism, strain on the nervous system from insomnia and the constant struggle for breath, dread of death,[5] uremia, acidosis,[7] and some unknown "toxic factor." Head, speaking of patients who had had transient delirious symptoms, offered the theory that reflected visceral pain was responsible for the delusions and hallucinations.[10] Some of the earlier writers held the theory that the location of the cardiac lesion determined the type of mental reaction. For example, Flint thought that indifference alternating with excitement and terror were most apt to occur in pericarditis, while imperfect sleep disturbed by frightful dreams was characteristic of valvular disease.[4] Curtin speaks of the belief that "the aortic cases are those of the excited types, and the mitral ones the depressed."[5] However, it is generally agreed at the present time that severe mental symptoms may be associated with

any type of heart disease, and that the mental symptoms do not bear any specific relation to the location of the cardiac lesion.[7, 9, 14]

The question of digitalis poisoning as a cause of the delirium deserves special attention, since this is brought up from time to time even today. In 1874, Duroziez advanced the theory that the mental symptoms were brought about by digitalis, and discussed 20 patients in whom delirium had appeared after digitalis had been started.[3, 12] Hall, in this country, expressed the same idea in 1901, but said even then that the majority of physicians did not consider the drug responsible.[12] Carr (1921) thought that digitalis acted as an additional toxic factor at times,[13] and in the same year Macht demonstrated that the various digitalis bodies produced a depression in the behavior of rats in the circular maze.[11] The experience of more recent writers does not confirm this theory,[7, 14] and we have found in our own series of cases in a mental hospital that adequate digitalization, by restoring compensation, is of definite benefit. It is possible that digitalis that had not been properly purified, and which was not standardized, might produce toxic symptoms either by direct action upon the central nervous system, or indirectly by allowing decompensation to increase, but with the present standardized preparations this should not occur.

Psychiatrists have frequently called attention to the fact that in addition to the physical effect of somatic phenomena such as disease or childbirth, one must also consider the psychological significance of these conditions. For example, what does cardiac disease mean to the individual? Everyone understands that the heart is a most vital organ, and when it is diseased it not only produces a physical incapacity, but may also contribute to the undermining of the spirit and morale of the individual. This very factor may be responsible to a large extent in the lowering of mental resistance and serve as a strong factor in producing mental disease. Although this point is mentioned occasionally in the literature, especially as regards the anxiety found in heart disease,[5, 16, 17] it would appear to be deserving of more attention. In most instances, the heart disease develops slowly, and the intelligent patient recognizes the seriousness of his condition. There is first the fear and dislike of being dependent upon others, and next the fear of death, as well as the constant sense of physical distress.

Another point which has not received sufficient attention in the literature is that of the personality of these patients. Riesman said: "The particular state of mind is closely related to the patient's temperamental make-up and to his philosophy of life," and commented on the fact that some patients with heart disease displayed an unusual patience and placidity even until the time of death, while others showed varying degrees of emotional instability.[7] It is recognized that the vast majority of patients with heart disease do not develop psychotic symptoms, and this has led some to believe that persons with different types of psychological tendencies react differently to the stress of the illness,[14] or that there may be a psychopathic predisposition.[16] The only method by which this question can be properly studied is by closer contact between the internist and the psychiatrist in the general hospital.

In making this study the writers have selected ten patients who were admitted to the New York Hospital-Westchester Division between 1916 and 1931, a period of 15 years. All these patients, six women and four men, were considered to have psychoses associated with heart disease, and were the only patients with this diagnosis admitted during that time. In comparison it may be mentioned that of 50 consecutive cases of heart disease admitted to one ward of a general hospital in a period of one year four of them (8 per cent) presented the clinical picture of "cardiac delirium." *

The background of the ten patients studied in the mental hospital is of some importance, for there were eight with a positive family history of cardio-vascular disease, and in seven of these the relationship was that of parents or siblings or both. In view of the close relationship, one is justified in saying that in addition to possible hereditary factors, these patients may have had more than the usual fear of heart disease because they had had the opportunity to observe its effects in persons close to them. The incidence of mental illness in the families of the patients was not marked, only five having a positive family history, and of these two were cases of senility which did not require hospitalization.

* Material from the medical service of the Peter Bent Brigham Hospital by permission of Dr. Henry A. Christian.

The average age of the 10 patients was 55. Due to the fact that all but one were past middle age when admitted, information concerning their early development was scanty. As far as could be determined their early development was not remarkable, and although there were the usual childhood diseases, there were no instances of delirium, nor did any of them capitalize their physical illnesses. Two were considered as having been rather frail in childhood. None presented any behavior problems in early life. The educational level of the patients was in keeping with their social and economic backgrounds. From the organic viewpoint there was no relation between occupation and the development of either heart disease or mental illness. All of the men had been successful in business and of the women, all but one had been considered very efficient, either in business or the management of their households. The four men had all married, and were said to have made good adjustments in married life. Two of the women were still single at the time of admission to the hospital, both had been unusually attached to their mothers and neither had shown much interest in men. Of four married women, three had married men who were passive and inefficient and they showed more attachment to their children than to their husbands. Two of the men had used alcohol to excess at intervals.

Of particular interest are the findings in regard to the personalities of our patients. The youngest was described as being of a placid contented nature, but all the others showed certain traits in common. All were persons who were rather ambitious, energetic, somewhat over-conscientious in work, and with a tendency to work under considerable tension. There were easily recognized feelings of inadequacy in four, and two who were not considered to have such feelings had histories of excessive alcoholism at times, which seemed to indicate a sense of inability to cope with their environments. Such expressions as "tense," "driving," "domineering," "always unusually energetic," "hard worker," "worked under pressure," and "the tense worrying type," occur with frequency in the histories of all the patients. In addition to these descriptive terms used by people who knew them, the occurrences in their lives would indicate such drives, for most of them had succeeded in spite of definite physical, social or financial handicaps.

On the other hand, in spite of their successes and superficial adjustments, close examination of their histories shows that seven of the ten actually had a great deal of emotional instability. The evidence for this ranges from such frank findings as hysterical reactions in adolescence and early adult life in one patient, to periodic drinking or expressions of inferiority in others, and finally, definite mood swings of such intensity as to call for comment from friends or relatives.

In studying the development of the mental illnesses which brought these patients to the hospital, it was found necessary to determine not only when heart disease had been first noted, but what the emotional reaction to this had been on the part of each patient. It has been stated previously that none of the patients capitalized their other illnesses, and this was found to be true for heart disease also. One, a woman of 31, had had known heart disease since an attack of chorea at 10. This had prevented her from engaging in any great physical activity, and at times had necessitated hospital care. She is said to have accepted her infirmity "gracefully," and one is inclined to wonder whether this attitude was not somewhat unnatural, especially when it was also found that she enjoyed sympathy. Another developed heart disease at about 18, but in spite of frequent periods of decompensation became a successful nurse, and never expressed worry over her condition. In a third, admitted to the hospital at 25, dyspnea had been noted after an attack of rheumatism at 23. She was not told that she had heart disease, and when given a rest treatment she thought she had tuberculosis and became greatly depressed and fearful. Among the four men, the symptoms of heart disease had begun after middle age, and all of them made attempts to ignore their incapacities, three showing a stubborn determination to continue work even when decompensated. In the three women who developed symptoms of heart failure after middle age, this same attitude was present.

There were other features of a somatic nature which had important psychological implications. Two of the patients had cataracts which were sufficiently advanced to cause a definite degree of difficulty with vision, and in one of these the psychotic reaction made its appearance when she went home from the hospital after an eye operation. Another had undergone limitation of her usual

activities because of deafness which had been developing over a period of several years. In a fourth, the cardiac decompensation began during her first pregnancy, and after delivery she was unable properly to care for her child. Two others had had severe bronchitis which had sometimes incapacitated them for work for several years before their cardiac and mental illnesses began.

Of equally great importance appeared to be those precipitating factors which might be considered as having purely emotional effects. In seven of the patients there were obvious instances of such things occurring in rather close relation to the development of the mental illnesses. One patient had been extremely unhappy since the death of a sister a year before, one had shown considerable depression after the death of her father within the year previous to admission, another had had guilt feelings about a love affair that had continued for four years and was abruptly terminated a few months before her admission, one had been worried over having to give up his home, and still another had been under much strain for a year trying to adjust to an unpleasant occupational situation. There were only three instances in which no precipitating factors of such a nature were found, and these patients were men who were ordinarily self-contained and had not unburdened themselves even to members of their families.

Since the number of our cases is too small for satisfactory statistical purposes, the average duration of cardiac decompensation before the development of the delirium cannot be accurately computed. One patient had shown signs of decompensation for only 21 days before admission to the hospital, and the serious mental symptoms had begun ten days before admission. Another had had cardiac symptoms which had disabled him for three years preceding admission, and had been mentally ill for one month when he came to the hospital. In general, our patients had been physically incapacitated for two to eight months before admission, and mental symptoms had been present to some degree for one to six weeks. In every case, the onset of mental symptoms was gradual.

There was a rather definite pattern in the development of the mental illness, but it must be emphasized that this organic reaction is not specific for heart disease and may develop in a similar way in association with other illnesses. In general, the first symptoms

were insomnia and restlessness at night, and some irritability and moodiness during the day. The symptoms gradually increased, and were followed by transient periods of confusion during which the patients might misidentify friends and relatives and show some disorientation. These periods would then increase in intensity and duration, there were increased talkativeness and restlessness, and the stream of talk would gradually begin to lack coherence. In each of the ten cases unsystematized paranoid ideas appeared, and the patients expressed such fears as that they were going to be injured, were being followed, or that members of their families were in danger. After this, auditory and visual hallucinations began to occur, agitation became extreme, talk was incoherent, rambling and occasionally limited to unintelligible muttering. Two of them made suicidal attempts. As a rule, they were not brought to the hospital until their agitation had become so marked that they could not be cared for at home even with the aid of special nurses.

In one patient the acute symptoms had developed with comparative rapidity, and she had been brought directly to the hospital. In the others, however, some form of drug sedation had invariably been attempted while the patient was at home and six of these had received narcotics, the dosages having been gradually increased as they failed to respond with sleep. One had received morphine, heroin and large amounts of triple bromides for a period of one month prior to admission. Bromides and chloral had been administered frequently for ten days to another. In none of the cases had the patients received the desired effect from these forms of sedation, but on the contrary, there had been an increase in mental symptoms following their use. Digitalis had been used in seven of the cases, five of whom had mitral valvular lesions, but only one had been digitalized. The remainder had been given small, unsystematized doses of the drug, which had had no effect in decreasing the decompensation. In general it may be said that we found a number of factors contributing to the development of the delirium rather than any single one. Among these were the physical and psychic effects of the heart disease itself, emotional strains brought about by other physical weaknesses or by difficult situations, and finally the excessive use of sedative and narcotic drugs, and unsystematized dosages of digitalis.

While the degree of mental illness on admission varied, all the patients showed the elements of the acute organic reaction. There was an extreme restlessness in every case, and many of them could be kept in bed with difficulty. This restlessness was particularly marked at night, as were all the other mental symptoms. Expressions of anxiety or apprehension were present in all of them at some time, although in two cases such feelings alternated with a mild euphoria. The stream of talk was usually rambling and incoherent, one had perseveration of speech, and three showed paraphasia. The next most common symptom was a fluctuation of the level of awareness. All of the patients were disoriented in some sphere at one time or another but it was striking to see the changes in this symptom. Patients who had been totally disoriented throughout the night, and whose attention it had been impossible to gain, would become mentally clear at intervals during the day, and not only appear to be well oriented but be able to converse coherently. Auditory and visual hallucinations were definitely present in six of the patients, absent in two, and could not be determined in two others.

While it was formerly believed that the trend of thought during delirium depended upon the type of cardiac lesion,[5] the findings in this series offer further confirmation of the more recent theory that in any organic reaction type the trend is determined by the pre-psychotic personality problems of the patient. The delirium frequently serves as a vehicle for the expression of conflicts, as shown by the belief of one patient that the wife and children of the employer to whom she was attached were waiting outside the door to kill her. These points are to be demonstrated more completely in the discussion of one of our cases.

The general physical findings in our cases may be mentioned briefly, since there was nothing unusual in any of them. Six of the patients had mitral valvular disease, of a rheumatic origin. Of these, three had auricular fibrillation and one had aortic insufficiency. Three, all men, had coronary disease, and the remaining patient's cardiac difficulty was of hypertensive origin. None of the patients had any known cerebral arteriosclerosis, and only three had peripheral involvement of the arteries. No cases were selected in which there was nephritis. Only those patients with coronary

artery disease, and the one with hypertension, showed elevations of the blood pressure. The degree of decompensation varied from orthopnea and marked generalized edema to nothing more than moderate cardiac enlargement and slight dyspnea on exertion, and there was no apparent relation between the degree of delirium and the severity of the heart disease. Four of the patients died in the hospital, and six recovered from the delirium and were discharged. The four who died were far advanced in decompensation and became semi-stuporous before death. Their deaths occurred within two to five weeks after admission.

The following case is representative of the study:

CASE 1.—This patient was a married woman of 46, who came to the hospital in a disturbed mental state and showing a marked degree of cardiac decompensation. The family history showed a tendency to the development of cardiovascular disease in the paternal line. A younger brother of the patient was mentally defective, and a younger sister developed a paranoid psychosis. The patient, who was the third of six siblings, had a normal and happy childhood, and did well in her classes. Her menses were established at the age of 13 and menstruation was regular and without complication. Nothing unusual was noted in her attitudes or behavior during adolescence. At 20 she graduated from normal school, and then taught successfully in a high school for three years. At 23 she married a brilliant and conscientious professional man who was five years her senior. There were four normal pregnancies, and all of the children were healthy. At the time of her admission their ages were 20, 18, 16 and 13 respectively. She had always been very tense and energetic and seemed to do everything under a great deal of pressure. In addition to being very efficient in the management of her household, she had many civic, social and religious interests. After her fortieth year, as her children grew older, these interests had increased. Although her attitude toward sexual matters had been that of a modest, reserved and somewhat prudish person, there was a brief period three years before admission when she had introduced her husband to a number of perverted sexual practices and following this had become frigid. Apart from the outstanding trait of tenseness, her only other personality problem had been a feeling of intellectual and social inferiority. The physical history showed that she had grown to be a very pretty and attractive girl. At 23, shortly after her marriage, she began having frequent attacks of tonsillitis. Sixteen years before admission to the hospital, when she was 30, there was an illness diagnosed as "rheumatism," characterized primarily by joint pains and three years later she had what appeared to have been chorea. After this she was in good physical health until three months before admission, at which time symptoms of heart disease appeared.

The illness which brought her to the hospital was precipitated by a number of factors in addition to the heart disease. From the psychological aspect, as

her youngest child grew older she began to show more push in her outside interests, talked of outgrowing her need in the home, and expressed a horror of growing old. Four years before admission she became attached to an erratic religious leader, idealized him and lost interest in her husband. During the last year of their acquaintance she imitated this man by taking many long, vigorous walks. About six months before admission, the pastor was forced to leave town, and three months later the patient had a sudden attack of dyspnea. Physical examination at that time revealed signs of mitral stenosis and insufficiency with auricular fibrillation. She was kept in bed for two weeks and digitalized. After this, she received a maintenance dose of 0.2 gr. digitalis daily, but it was impossible to get her to take sufficient rest. She showed a little more interest in her husband and her home until three weeks before admission. At that time, while waiting for her youngest son to have a minor operation, she suddenly collapsed, complained of weakness and said that she was "mixed up" and the "nerve of responsibility had snapped" in her head. She asked her husband to cut off her head, became noisy and tried to make vague confessions of her affair with the religious worker. She held her body in tense positions, acted as if she were being kissed, and talked of hearing the voice of the minister. Appetite and sleep were poor, and she was given such hypnotics as luminal before admission.

On admission she appeared toxic and dehydrated, and her lips and tongue were dry. The heart was enlarged, there was mitral stenosis and insufficiency with auricular fibrillation, and the pulse rate was over 100. The lungs showed signs of congestion at both bases, liver was somewhat enlarged, and the ankles were edematous. Blood pressure was 128/72. Neurological and gynecological examinations showed no pathology. Blood cytology, serology and chemistry were normal and the urine contained only traces of albumin. Mentally she was overactive, thrashed about in bed, assumed erotic postures, and smiled. She thought she heard the voice of the religious worker telling her children about sex, and had visions of airships and large white, fluffy birds. She thought she was receiving wireless messages. Her mood was changeable as shown by alternations from laughter and giggling to anger and defiance. During the day she was fairly well oriented, but at night there was confusion and misidentification of those about her. Her remote memory was good, she realized that she was mentally sick and begged for rest.

She was kept in bed for eight weeks after admission, fluids were given freely for the first week, then fluid intake was limited, and she was given a low salt, low protein diet. Digitalization was brought about in a few days by the use of 15 minims of tincture of digitalis every four hours. This dosage was then decreased to 10 minims three times a day. Elimination was aided by enemata every other day. For the first three weeks she showed a degree of fever in the evening. During the second week her overactivity decreased and she slept well at night. After the third week her hallucinations disappeared, but for the next two weeks she was suspicious and apprehensive, believed that the physician read her thoughts and that she was influenced by electrical waves. After the sixth week her suspicions disappeared, there was no evidence of decompensation, and she was allowed to sit up. At the end of

eight weeks she was able to be out of bed and the digitalis was discontinued. Her activities were gradually increased. She was able to talk about her past life, and discussed her conflicts frankly with the physician. Her husband had an understanding attitude, and interviews with them together helped in bringing about a better mutual understanding. Her improvement continued and she left the hospital four months after admission. The action of her heart was regular and there were no evidences of decompensation. She was advised to keep in touch with the physician who had treated her before admission, and who was familiar with her psychological difficulties. When last heard from six years after discharge, she was still in good mental and physical health.

Discussion and Management.

This case illustrates very well the combination of factors contributing to the mental illness. In the background one sees the usual infections associated with the development of cardiac valvular disease, in a tense, driving, energetic woman who had an underlying feeling of insecurity. Superimposed upon this were outstanding difficulties appearing in her early forties, five years before admission to the hospital. She expressed a horror of growing old, and carried on increased activities with much push and tension. Then came the affair with the religious worker, and in her emulation of him by taking long, vigorous walks, the direct effect of one of her personality drives in reducing her cardiac reserve is obvious. Her collapse while waiting to hear from her son who was undergoing an operation has a deeper psychological significance than was reached with the patient, but her behavior and talk immediately afterward when she spoke of the "nerve of responsibility" breaking, and of wishing to be decapitated by her husband, as well as the vague confessions, showed a conflict. Her behavior in the delirium was erotic, and her talk gave evidence of a sense of guilt and the need for punishment at the hands of the husband to whom she considered herself unfaithful. This harked back to a psychological situation of years' duration, a situation in which there was a definite strain upon the individual as a whole.

The management of this patient illustrates the treatment in general. In this case, rest was the first factor to be considered. This was accomplished by keeping her in bed for a long period of time. No hypnotic drugs were given, and during the day she willingly stayed in bed. At night, when there was increased restlessness and

apprehension, it was found that a special nurse was usually able to control the patient and where this was impossible, prolonged baths were given. Since she appeared dehydrated on admission, and had had sedative drugs, she was at first allowed to take fluids freely, and elimination was aided by the use of enemata. There had been insufficient digitalization, therefore she was given enough digitalis to aid her heart in regaining compensation. A diet that could be easily assimilated and would improve the state of nutrition was given. As there was improvement she was allowed to be up, and her physical activities were gradually increased in keeping with her ability. The patient stayed in the hospital long enough to discuss her emotional problems with her physician, and was thus aided in making a better adjustment after discharge. That this last point in treatment is of considerable importance in the management of any case of heart disease is borne out particularly well by the studies of Dunbar and others.[17, 18]

Summary.

1. Some of the literature on the subject of psychotic reactions associated with heart disease has been reviewed.

2. The greater incidence of such reactions in general hospitals than in psychiatric hospitals has been indicated.

3. An analysis of ten cases seen in a psychiatric hospital has been made, and it has been shown that the occurrence of delirium is conditioned to a great extent by psychological personality factors, as well as the features of decompensation, inadequate medical treatment of the heart, and excessive drug sedation. This point has been illustrated by a detailed summary of the case of one patient.

4. A general method of management of such illnesses has been suggested, with emphasis upon rest, proper elimination, absence of hypnotic drugs and proper digitalization. This should be correlated with psychotherapy to obtain the best results.

DISCUSSION.

DR. DEXTER M. BULLARD (Rockville, Md.).—This paper really begins with the question, What does cardiac disease mean to the patient? For in anxiety states, such as deliria, this comes to the foreground.

The doctor touches on that when he emphasizes the fear that the patient has as to what cardiac illness means, and second, the dislike of being dependent on others.

Although not especially emphasized in the paper, I believe that is rather an important part of the background of why a delirium appears in cardiac disturbance, the fear and dislike of being dependent on others, for it cannot help but produce a great deal of anxiety.

A second point that I think deserves emphasis is that in eight of these ten patients they had an opportunity to be exposed to cardiac illness in some

member of the family, so that leaving out entirely any hereditary factors we do have a psychogenic trauma which cannot help play a part, particularly if the patient has been in close association with the relative in nursing and taking care of the elderly sick.

In a recent paper of Dunbar-Wolf, the fact was stressed in particular with cardiac cases, and they mention that an exposure of this kind, a social exposure to someone with cardiac illness, was just as important in the history as was exposure to tuberculosis in a member of the family.

Without question, cardiac deliria depend upon the pre-psychotic personality. All of these patients showed unsystematized delusions of persecution. Ten is not a very large number, but if you find 100 per cent of any group of people, no matter how small, it is worth thinking about, and certainly one with paranoid ideas has a great deal of underlying insecurity which, when the lid is blown off through cardiac stress, cannot help but produce a psychosis.

Inasmuch as these patients were better oriented during the day than at night, I imagine that a great deal of psychotherapy went on in the mere routine jotting down of their productions and the attempt to discuss with the patients even in the deliria, when they were not theoretically in contact, probably was quite a factor in helping these patients to recover.

From the standpoint of therapy, the usual medical measures such as anyone would employ, are resorted to. I think if the problem of anxiety is appreciated and discussed with the patients even, as I say, when they are theoretically not in contact, a good deal of the anxiety can be alleviated, and with that comes a lessening of the load on the heart and improvement of the somatic disability.

Dr. Frank Luton (Nashville, Tenn.).—There is a small group of cardiac deliria that developed after-compensations, going along nicely. The patient has not shown any evidence of a delirious state, and after digitalization, of a few days, the patient then shows a delirious reaction that I would call a cardiac delirium.

I would like to ask if the speaker would include such in that group of patients, and if he has an explanation, or if he would say what are the principal factors involved.

Dr. Clarence O. Cheney (White Plains, N. Y.).—I would like to emphasize the point Dr. Bullard made, that patients who have cardiac disease may have what has been called by Dunbar and school, a shoot-over heredity. These persons are brought up perhaps in an atmosphere of anxiety, regarding heart disease with the prospect that they may sooner or later eventually develop serious difficulty and die of it, and it is no minor or trivial situation, I assure you.

Another thing that has been emphasized is that persons who have real organic heart disease tend to minimize those symptoms and, as Dr. Drewry has pointed out, tend to keep on with their work, and that is a diagnostic differential point from the neurotic person who complains of heart symptoms

and who, rather than covering up or minimizing the heart symptoms, tends to exaggerate them.

Dr. Bullard mentioned the fact that these patients, when they were awake during the daytime, seemed more clear than at night. Those of you who recall Dr. Hoch's description of the organic delirium in 1917, will remember that the description Dr. Drewry has given of these cardiac cases corresponds almost word for word with Hoch's description of the organic and particularly cardiac delirium.

Hoch felt that the reason these cardiac persons or patients are clear in the daytime is that they have more stimulation then; whether it is psychotherapy or not, whether they are being definitely treated or not, the fact of the daylight, the fact that they can see things and people going around, tends to keep up their levels of consciousness, whereas during the nighttime it tends to dip down, as Dr. Hoch used to say, to a much lower level when they are out of contact.

Another point is to emphasize the importance of not giving sedatives and causing further difficulties with these cardiac patients. The patients that were received in the Westchester Division had a very serious complication of at least a partial drug delirium and had to be treated first for that.

Unfortunately it is a tendency of the general practitioner, to use sedatives on those cardiac cases as well as other disturbed cases, with a production of a complication of a drug delirium in which the patients may die if they are not definitely and intensively treated for that drug reaction.

It makes the treatment of the cardiac cases much more difficult and complicates the whole picture. Perhaps Dr. Drewry can answer the question that has been asked better than I can, regarding the development of apparent toxic delirium after compensation has been established. I think it may be frequent that compensation has been established by digitalization, but also, with the continuation of the administration of digitalis, the toxic state developed which is a digitalis intoxication and not a cardiac delirious reaction.

Dr. Patrick H. Drewry.—In regard to the comment regarding the small number of cases made by Dr. Bullard, I feel that this is valid and that this limited number cannot be used for statistical purposes. It emphasizes the fact that illnesses of this type can best be observed in the general hospital, and where the psychiatrist can have access to them.

We have had no cases of delirium after compensation had been restored in our series. However, I have noted such in a general hospital. I felt it was due to the excessive quantity of drugs given (as a rule, morphine is given rather heavily), and also to the fact that, as a rule, fluids are limited considerably in treating patients with decompensation. It seems to me this would allow a toxic state to arise.

I do not believe that digitalis would cause it, except perhaps in individuals who had some sensitivity to digitalis, which of course would be difficult to decide upon.

THE BEHAVIOR OF CHILDREN RECEIVING BENZEDRINE.*

By CHARLES BRADLEY, M. D., East Providence, R. I.

The use of benzedrine (beta-aminopropylbenzene; benzyl methyl carbinamine) as a central nervous system stimulant has recently aroused considerable comment. A number of reports are now available describing its effect upon the mood and other psychological reactions of adults,[1-7] but so far no one appears to have studied its effect upon the behavior of children. Since the psychological response of children to drug therapy of any sort appears to have been a generally neglected subject,[8] and since some of the changes produced by benzedrine in adults are of a type which might theoretically prove of clinical value in certain behavior problem children, the present studies were undertaken at the Emma Pendleton Bradley Home.

The facilities of this institution[9] are admirably adapted to the observation of children's behavior under controlled conditions without introducing the artificial distractions of a laboratory situation. The hospital deals only with resident patients of normal intelligence, the majority being children under 12 years of age presenting neurological and behavior disorders. Since such children require prolonged treatment the hospital setting has been designed to provide most of the desirable features of an outside community, including school, scouting activities, sports, etc. Although each child busies himself with a very natural sort of daily activity, he is under constant observation, and careful records of his behavior are kept as a matter of routine. In general, the patients are quite unaware of this close scrutiny.

To observe the effect of benzedrine upon the behavior of children, 30 patients, already resident in the hospital, suffering from a variety of behavior disorders, were selected for study. Every child in this group had already been under observation for at least

* From the Emma Pendleton Bradley Home.

Portions of this study were made possible by a grant from the Committee for Research in Dementia Præcox founded by the Supreme Council, 330, Northern Masonic Jurisdiction, U. S. A.

a month. Twenty-one boys and nine girls were studied, this ratio of sexes approximating that noted for all admissions to the hospital. The ages ranged from 5 to 14 years, two boys and one girl having passed their 13th birthday. The children's behavior disorders were severe enough to have warranted hospitalization, but varied considerably. They ranged from specific educational disabilities, with secondarily disturbed school behavior, to the retiring schizoid child on the one hand and the aggressive, egocentric epileptic child on the other. The patients' intelligence was in general quite within the so-called "normal" range.

In addition to routine observation and recording of behavior by ward nurses and teachers, each child was personally observed for a period of three weeks by a special psychiatric nurse. Because this nurse's customary duties had already involved daily close association with all of the children, she was able to observe carefully each patient without his recognition of her special function at this time. During the second week of observation a daily morning dose of benzedrine [10] was administered to each patient upon arising. Later the records of his behavior during this week were compared with those of the week prior and the week following, which were taken as control periods for this particular child.

School Performance.

Possibly the most striking change in behavior during the week of benzedrine therapy occurred in the school activities of many of these patients. Fourteen children responded in a spectacular fashion. Different teachers, reporting on these patients, who varied in age and school accomplishment, agreed that a great increase of interest in school material was noted immediately. There appeared a definite "drive" to accomplish as much as possible during the school period, and often to spend extra time completing additional work. Speed of comprehension and accuracy of performance were increased in most cases. Insight into school improvement was generally present, though few of the children attributed it to the medication they had received earlier in the day. The improvement was noted in all school subjects. It appeared promptly the first day benzedrine was given and disappeared on the first day it was discontinued.

There were 15 children who did not show so striking a change, and one child who was not of school age. Of the 15, eight did show some improvement, accompanying other temporary changes in their personal characteristics. Five others showed no change in school performance, although their behavior in other respects was distinctly altered. Two children showed no response to the drug in school or elsewhere.

Emotional Response.

In discussing emotional responses it must be kept in mind that in many of these children the conduct disorder was essentially an external symptom of emotional maladjustment. Fifteen of the 30 children responded to benzedrine by becoming distinctly subdued in their emotional responses. Clinically in all cases this was an improvement from the social viewpoint. In many it was accompanied by a sense of well-being; but superficially the appearance was that of a child whose mood swings had become diminished. In this group were some children who had expressed their irritability in group activities by noisy, aggressive, domineering behavior. Such children under the influence of the drug became more placid and easy-going. Coincidentally, they seemed to become more interested in their surroundings. Such changes, however, by no means paralleled the improved school performance noted above as only seven children were common to both groups.

A variety of emotional responses were noted in the remaining 15 children. Seven of them gave evidence only of a sense of well-being, even to the point of mild euphoria. Although questioning the children in regard to their subjective feelings was studiously avoided in all instances, spontaneous remarks such as, "I have joy in my stomach," "I feel fine and can't seem to do things fast enough today," "I feel peppy," "I start to make my bed and before I know it, it is done," and "I feel fine," seemed significant. All of these patients showed a widening of interest in things around them, and superficially at least, a diminished tendency to be preoccupied with themselves.

Three other patients were observed to cry much more easily during the week that they received benzedrine, as though their emotions were more easily aroused. Two others were noted to wear

worried expressions quite foreign to their usual appearance. Only one child of the entire 30 responded to the medication by becoming more hyperactive, aggressive and irritable.

As was the case with alterations in school performance, all these changes appeared promptly on the first day of treatment and disappeared as soon as the drug was stopped.

Other Psychological Changes.

A drug whose action is that of a stimulant may naturally be expected to produce changes in motor activity. In children, however, it is extremely difficult to measure motor activity *per se* apart from the individual's general behavior as shown by his mood and his intellectual activity. In our patients some decrease of motor activity was usually noted in the children who became emotionally subdued. A few of those who responded with elation possibly became a little more active, particularly in their daily routine about the hospital. Only three patients showed an increase in motor activity not explained by other changes. These three boys became active to the point of agitation, ran about rather than walked, talked more rapidly, and in general were so stimulated as to interfere with the efficiency of their daily work in school and on the ward. One of these was the child who became noisy and defiant.

Another boy, previously mentioned as having a worried expression, and also included among the three whose motor activity increased, expressed feeling of agitation and worry, was afraid to go out for fear he might run away, and was at times fearful of death. He had not manifested such symptoms before.

It will be noted that comparatively little mention has been made of the patients' subjective feelings under the influence of benzedrine. Personal questioning of any child was deliberately avoided so as not to influence his behavior artificially through suggestion or by indicating that he was the object of particular attention. Records of subjective responses are therefore limited to the occasional spontaneous remarks which the children made, and which have already been mentioned.

Physiological Observations.

In view of the observations of others that certain physiological changes [1, 6, 11, 12] may follow benzedrine therapy, such routine ex-

aminations as would not artificially influence behavior were carried out during these studies. On the doses of benzedrine which were given blood pressure was noted to rise moderately but inconstantly during each day on about half the children. There was no significant change in the erythrocyte count or hemoglobin level as a result of the week's treatment. Body weight was not appreciably influenced. In six of the 30 children nocturnal sleep was mildly disturbed, as evidenced by a delay in the time of falling asleep for the first night or two. One patient remained awake to a late hour for four nights. Loss of appetite and nausea at the time of the morning meal were observed in a few of the children at the start of the experiment. Intolerance of the conventional dose when present was uniformly expressed by malaise, nausea and epigastric distress, persisting for an hour or two, and usually relieved by rest. Agitation and irritability, said to be characteristic of overdosage in adults, were observed in but one child.

Duration of Effect.

Psychological effects were noted to appear in the majority of the children 30 to 45 minutes after oral ingestion of the drug. Behavior changes were at their height during the second and third hours, with gradual disappearance over a period of 6 to 12 hours. Occasional sleep disturbances 16 or more hours after the morning dose suggested that in a few individuals the stimulating effect was more persistent. In all instances the full effects appeared on the first day of administration, continued daily throughout the week and disappeared permanently as soon as the drug was discontinued.

Dosage.

The 30 children who were the objects of this study received single morning doses of benzedrine sulfate upon arising. It was found, on the basis of giving gradually increasing trial doses to a few of the children, that 20 mg. was generally a satisfactory amount to produce changes in behavior without undesirable physiological consequences. All the children studied were then given a trial dose of 20 mg., but in eight instances this resulted in gastrointestinal distress sufficient to color all the child's reactions. These eight children were therefore given 10 mg. as their daily dose during the

week. Two of them showed no response of any sort on this amount, suggesting that the largest dose they could tolerate was therapeutically ineffectual. The remaining patients all received daily doses of 20 mg., except one boy who tolerated 30 mg. very well and received that amount. There was no apparent relationship between the children's ages or weights and their reaction to benzedrine.

Comment.

Possibly the most spectacular change in behavior brought about by the use of benzedrine was the remarkably improved school performance of approximately half the children. This is the more striking when we note that these patients were of good intelligence and that they were receiving adequate attention for any personality disorders which might affect their school progress. Moreover they were already in a school where specially trained, sympathetic teachers dealt with their pupils either on an individual basis or in very small groups. To see a single daily dose of benzedrine produce a greater improvement in school performance than the combined efforts of a capable staff working in a most favorable setting, would have been all but demoralizing to the teachers, had not the improvement been so gratifying from a practical viewpoint.

No entirely plausible reason for this acceleration of school performance is evident aside from the fact that a stimulating drug was used. However, at least half of the whole group of children did not show this striking response in school, in spite of the fact that most of them responded in other ways to the medication. Only half of the group showing favorable mood changes shared to a notable degree in the school improvement.

As far as improvement in individual school subjects was concerned the teachers were most impressed by changes in arithmetic performance, since speed of comprehension, degree of accuracy and quantity of output were all favorably affected.

It appears paradoxical that a drug known to be a stimulant should produce subdued behavior in half of the children. It should be borne in mind, however, that portions of the higher levels of the central nervous system have inhibition as their function, and that stimulation of these portions might indeed produce the clinical picture of reduced activity through increased voluntary control. Pre-

sumptive evidence that this may be the case is suggested by electroencephalographic studies,[13] which formed part of the clinical examination in 20 of our 30 patients. Definite abnormalities of the brain rhythms were noted in 11 of these children, eight of whose records showed the " spike and slow wave " form characteristic of the " seizure waves " seen in patients with petit mal epilepsy [14] and in some children whose erratic, irritable and aggressive behavior resembles that of epileptic patients.[15, 16] It may be significant that all but one of these children with " seizure waves " became distinctly subdued under the influence of benzedrine. Since it has also been noted that " slow waves " in the electroencephalogram are likewise present in a number of conditions where consciousness is impaired, it has been suggested that their appearance indicates impaired cortical functions.[17] One might postulate that a stimulating drug like benzedrine may tend to arouse this impaired cortical activity and alleviate any behavior disorder resulting therefrom. Further studies are necessary to confirm this.

There are, of course, a great many other possible factors entering into the genesis and clinical manifestation of any child's behavior problem. Complete understanding of the fact that children vary in their response to benzedrine awaits correlation of this variability with these many factors. From preliminary observations of the 30 children in this series there seems to be very little apparent relationship between a child's response to benzedrine and the conventional clinical characteristics of age, sex, past history, physical condition, reaction type, intelligence and special mental abilities or disabilities.

In spite of the attractive results obtained in this small group of patients, and the apparent low toxicity of the drug as evidenced by its prolonged use in the hands of other observers,[6, 7] it seems wise to await more complete knowledge of the action of benzedrine before recommending its clinical use in behavior problem children. Presumably the uncomfortable, though not necessarily dangerous, gastrointestinal symptoms which accompany overdosage indicate that the drug should be administered only by the experienced physician. The factors involved in children's behavior disorders are so many and varied that they can be competently evaluated only by physicians adequately trained in child psychiatry.

Any indiscriminate use of benzedrine to produce symptomatic relief might well mask reactions of etiological significance which should in every case receive adequate attention.

Summary.

The psychological reactions of 30 behavior problem children who received benzedrine sulfate for one week were observed. There was a spectacular improvement in school performance in half of the children. A large proportion of the patients became emotionally subdued without, however, losing interest in their surroundings. A variety of other definite behavior changes were also noted. Dosage, unfavorable responses, and duration of effect of the drug are discussed, and it is suggested that its use in the treatment of children with behavior disorders be supervised by physicians trained in child psychiatry.

THE EFFECT OF BENZEDRINE SULFATE ON THE INTELLIGENCE SCORES OF CHILDREN.*

By MATTHEW MOLITCH, M. D., Philadelphia, Pa.,
AND
AUGUST K. ECCLES, M. S., Jamesburg, N. J.

Benzedrine sulfate (benzyl methyl carbinamine) has been noted by Peoples and Guttman,[1] Myerson,[2] Nathanson,[3] and others to have a stimulating effect psychologically. A feeling of exhilaration and a sense of increased energy and capacity for work were noted in adults. Sargant and Blackburn [4] investigated the effects of benzedrine on 48 adult patients in a mental hospital, using Cattell's intelligence tests, and noted an 8 per cent improvement in the test scores. They hoped that their results would stimulate other clinics with adequate facilities to study a more homogeneous group with varying doses.

Ninety-three boys, between the ages of 11 and 17 and of varying mental levels, were examined with a battery of tests before and after medication. Table 1 gives the distribution of our cases according to age, color and mental level. Approximately one-half of our boys were given a placebo instead of benzedrine in order to ascertain the degree of suggestion. The placebo in every way resembled the benzedrine tablet physically as both were stamped out in the same tablet machine. Our cases are all inmates of the New Jersey State Home for Boys, and were committed by court because of juvenile delinquency. They did not have the serious mental deviations which were present in Sargant and Blackburn's [4] cases.

We were unable to express our results in a percentage deviation from the control intelligence quotients (I. Q.), as did Sargant and Blackburn,[4] because of the variety of tests we employed. On the other hand, we were able to study the effects of benzedrine on the motor, psychomotor and verbal responses of our subjects. All of the subjects of the experiment underwent the following tests: strength of grip, motor coordination, memory for designs, and one

* From the New Jersey State Home for Boys and the Department of Neurology, School of Medicine, University of Pennsylvania.

We wish to thank Mr. R. W. Webb of the Smith, Kline and French Laboratories for supplying the benzedrine sulfate.

of three highly standardized verbal intelligence tests. These three general intelligence tests were used to fit the wide variety of mental levels known to be present in the group.

A brief description of the tests used is given below. The strength of grip was tested by the Smedley dynamometer. A single trial with each test was allowed. The score recorded was the average "pull" of both hands expressed in kilograms.[5] In the Witmer form board test, each subject was allowed three trials according to the procedure described by Young.[6] Two scorings were recorded

TABLE 1

Totals.....	93	57	36	45	48	30	33	30

* The average normals had an I. Q. of 90 or above; the inferior normals between 75 and 90; and the subnormals below 75. For the white boys the I. Q. ranged from 58 to 107; interquartile range, 67-90; median, 80. For the colored boys the range was between 60 and 111; interquartile range 69-88; median 80.

for this test; the shortest time taken for any of the three trials and the total time taken for all three trials, the scores being expressed in seconds. In the memory for designs,[7] four cards bearing unusual designs were exposed for 10 seconds each. After each exposure, the subjects were given time to reproduce with paper and pencil what they saw and the scores were expressed in points. In the Kent E. G. Y. test[8] of general intelligence, an oral questionnaire was used as it is especially suited for illiterate subjects. The scores were expressed in mental ages. In the Morgan intelligence test,[9] the subjects were given alternate A and B forms. In these tests, the subjects write their answers, and the scores ob-

tained were expressed in mental ages. This test is quite adaptable to children of inferior general verbal ability as well as to the more capable. The Kuhlman-Anderson intelligence test [10] is similar and discriminative. The scores with this test were also expressed in mental ages.

Every boy received the three motor and psychomotor tests and, in addition, one of the above-mentioned verbal intelligence tests. The subjects were tested in fairly homogeneous groups of five or six at a time. We received excellent cooperation as our boys are accustomed to receiving tests. Control tests were given each subject, and about 40 days later he was retested, one and one-half hours, after either a placebo or benzedrine tablet was ingested (10 mg.). The psychologist giving the tests did not know which of the boys received the placebo or benzedrine. Records were kept of unfavorable reactions, and it is interesting to note that more were observed among the boys receiving the placebo than among those taking the benzedrine. Dizziness was noted twice in the boys receiving benzedrine while not at all in the placebo group. Nervousness was observed more often in the placebo group. The boys were retested again about 40 days later after two tablets (20 mg.) of placebo or benzedrine were ingested. Thirty-eight boys were again retested after being given three tablets (30 mg.) of placebo or benzedrine. In this last group, the Morgan intelligence test was not given.

Table 2 gives the results of our study. These results are expressed in percentage change from the median of the scores of the control tests. With few exceptions, there was found to be an improvement in the scores after both the placebo and the benzedrine were ingested. In previous experiments with placebos, we have always found an improvement due to its psychological effect. This effect was not noted in Sargant and Blackburn's group.[4] The children taking the benzedrine showed a greater improvement over those taking the placebo, but not to the same extent as that found by the aforementioned authors.

Summary and Conclusions.

Ninety-three boys between the ages of 11 and 17, and of varying mental levels, were tested at intervals before and after a placebo or benzedrine sulfate were ingested. Both groups improved their

scores, the children tested after taking benzedrine exhibiting a greater improvement than those taking a placebo.

A PSYCHIATRIC STUDY OF RECIDIVISTS.*

By CHARLES B. THOMPSON, M. D., New York City.

Civilized societies have long pointed to the seriousness of the problem formed by the recidivists or repeater criminals. One of the earlier works on the subject bears this striking title: "Britain's Blot, Recidivism: Habitual Criminality, and Habitual Petty Delinquency; A Problem in Sociology, Psycho-Pathology, and Criminology."[1] Different authorities[2] have said that some 48 per cent to 70.8 per cent of the prisoners in any given court are repeaters; in the Court of General Sessions they comprise about 50 per cent to 60 per cent. They have been described as "habitual," "persistent," "chronic" offenders; the general feeling among those who have most to do with them has been that they are *wilfully* antisocial.

The causes of repetition have been considered by criminologists to be as follows; unfavorable home or neighborhood environment; poor school adjustment; association with older criminals either on the street or in prison; lack of economic opportunities; or some form of psychopathology in the individual. All of these theories, however, while accounting in part for crime, do not go deep enough, and it is generally conceded that they are open to very serious questioning. When the unfavorable conditions are reversed, many individuals do not alter their behavior. Also we find that some children from good schools and apparently favorable economic circumstances take up antisocial lives, while from the slums have

come many of our most reputable citizens. When the antisocial individual is offered an opportunity at a regular task, he is apt soon to sicken of its monotony and turn against it. This is common knowledge among students of crime, and the authorities are unanimous in their observation that the commonly ascribed causes of crime do not account for the permanence of the antisocial reaction in the individual and that there is need for still further study.[3]

Our studies in the Psychiatric Clinic of the Court of General Sessions in New York City indicate that a repetition of crime proceeds from a certain automatic behavior pattern or set-up in the individual organism which will react whenever the appropriate and familiar stimuli are encountered. This pattern is apparently not altered by imprisonment or punishment, no matter how often imposed or how long, nor do our present methods of re-education influence it.[4] The individual seems unable to take up new ways of livelihood.

In an earlier article,[5] I mentioned that beneath all crime there exists what is commonly known as aggressiveness or competition. I indicated that this reaction of competition obtains also in the lives of all of us—in business, sports, diversions and family con-

[3] The National Commission on Law Observance and Enforcement (Wickersham Commission) submitted its exhaustive report for 1931 with this striking initial statement: "We find it impossible comprehensively to discuss the causes of crime or factors in non-observance of law. Criminology is remaking, the social sciences are in transition, and the foundations of behavior are in dispute."

Sheldon Glueck in "One Thousand Juvenile Delinquents" (1934) states: "May it not well be that the fiber of criminality is much tougher than we have thus far believed and that its tangled roots lie deeper than we have over-optimistically assumed? . . . . Great humility on the part of all concerned with this colossal problem is called for. . . . . We cannot have too much thorough-going research into fundamentals."

William Healy and Augusta F. Bronner in "New Light On Delinquency and Its Treatment" (1936) state: "Altogether it can be seen that our research into fundamental causes has left us with the conviction that the checking of a delinquent career once started is no easy matter."

tacts—and has an equally pathological obsessive quality. I endeavored, therefore, to bring out that a comprehensive study of crime includes all those factors in man's make-up which enter into his feeling and thought-processes to cause the reaction designated as competition.

In pursuance of this trend, a study of all the repeaters in the Court of General Sessions for the year 1935, namely, 1380, indicates certain interesting facts. The psychotic repeaters numbered only .6 per cent. This shows very little increase over the proportion of total insane in hospitals for mental disease to the total population

TABLE I.

MENTAL DEFECTIVE REPEATERS GROUPED ACCORDING TO AGES AND NUMBER OF OFFENSES.

No. of offenses	2	3	4	5	6	Total
Age Groups						
16-20	7	3	0	1	1	12
21-25	5	0	0	1	0	6
26-30	2	6	1	2	2	13
31-35	1	0	1	0	0	2
36-40	1	0	0	0	0	1
41-45	0	1	0	0	0	1
46-50	0	1	0	0	0	1
Total	16	11	2	4	3	36

for 1935, namely, .3 per cent.[6] The defectives among the repeaters numbered only 36 which is 2.6 per cent of the total. The correlation of age and recidivism among the defective repeaters is shown in Table I. Individuals with psychopathic personality among the repeaters numbered 5.6 per cent. Table II shows the recidivism of the repeaters with psychopathic personalities. These figures for the repeaters are essentially the same as for the whole clinic population for four years,[7] and total only 8.8 per cent. Therefore, we must look to the remaining 91.2 per cent for the essential question of recidivism. Table III shows the distribution of the repeaters by age-groups as compared with first offenders.

TABLE III.

COMPARISON OF ALL REPEATERS WITH FIRST OFFENDERS, ACCORDING TO AGE-GROUPS.

In Table IV we have listed all of the repeaters, exclusive of the psychotic, mentally defective and those with psychopathic personalities, who were examined in the Clinic in the year 1935, as compared with the first offenders of that year. We have made our estimate on the basis of convictions only, so that no individual is called a repeater merely because he has been in Court on previous

NOTE.—The coefficient of contingency showing the correlation between the number of arrests and age is .25. This shows a very slight correlation in excess of what would be expected on a basis of pure chance. It indicates that the number of arrests increases slightly with increase of age but this probably indicates nothing more than that it requires time to acquire a record of several sentences.

Another table not given here in which the age-groups and number of offenses have been "telescoped" shows this more definitely. The age groups have been merged so that we have one group containing those below 40 and another of those above. The individuals grouped according to the number of offenses have been merged into first offenders and repeaters (two or more). This table shows a trend toward a greater concentration of recidivism in the lower age groups. This indicates still less correlation between age and number of offenses.

While the number of convictions is no accurate index of recidivism, since more serious crimes usually incur longer sentences and hence are less apt to be repeated, nevertheless it serves as a rough index of recidivism. The first offenders are also listed for comparison.

occasions. This makes the first offenders some 15 per cent higher than they would be as calculated on the other basis.

It is first to be noted that the total number of defectives is only 36, namely 2.6 per cent of the total. Furthermore, the defectives practically disappear from the ranks of recidivists above the age of 30. By far the largest proportion of the defectives are among the second and third offenders.

The most striking fact in Table II is the large number of recidivists with seven or more offenses. They are nearly half the number of those with only two offenses. The psychopaths show a high degree of recidivism. Their total number, however, is proportionately small, only 5.6 per cent of all the recidivists.

In Table III the curve of age distribution of the recidivists follows very closely that of the first offenders. At the age of 45 and beyond, the number of the chronic offenders drops below that of the first offenders. We are not prepared to give at the present time the explanation for this marked falling off of chronic offenders, but it is possibly due to the fact that many of them are incarcerated and others may have succumbed to disease or accident.

Most important of all, Table IV shows that when we calculate the correlation between age and the number of convictions among the recidivists, age has very little to do with the matter. Expressed in another way, we find that recidivism is about as much a function of youth as of age. As a matter of fact, the antisocial individual very often shows his unwillingness or inability to adapt himself socially at a very early age.[8] *We may find the repeater reaction fully established at 18 as well as at 38.* Usually the antisocial adaptation is set up so early that the individual does not care to learn a trade and hence has no means of earning any but the most meagre living and this at hard labor. Different individuals show the repeater reaction in varying forms; for instance, one may be a repeater at picking pockets, another at burglarizing flats, a third as a large scale swindler,[9] or a fourth as a hijacker or hold-up man. Though the external forms or mechanisms of the antisocial reaction may vary widely, the central situation is, however, essentially the same.

A characteristic case history from my records is as follows:

The defendant is about 23 or 24 years of age. His father was a chronic alcoholic. As a boy he was a truant and was in trouble for two or three years

[8] This agrees with findings of Healey (The Individual Delinquent, p. 10), Glueck (*op. cit.*), Burt (The Young Delinquent, p. 19), Halpern (Studies of Recidivism in Yearly Reports of Probation Department of Court of General Sessions for 1933, 1934 and 1935), and others.

[9] Drs. Walter Bromberg and Sylvan Keiser present an extensive discussion of the mechanism of the swindlers in their paper: "A Psychologic Study of the Swindler."

in school on this account, and was finally sent to a truant school. Some time after leaving, he committed several minor larcenies and was sent to a reformatory. He later committed a serious burglary and received a sentence of several years. At the present time, he re-appears in the court after being released only some 6 or 8 months. He states that, on leaving prison, he got some work with considerable difficulty, but, "like everything else, I soon got tired of the job and quit." He has not been able to get one since. One evening, he felt "disgusted," probably somewhat depressed, and as he was going by an apartment house, went up through the stairway and down a fire-escape and burglarized a couple of apartments. He casually rode away on a trolley car and was intercepted by the police a few blocks further on.

Another man is aged 38. Likewise a product of a "broken home," his activities have been that of a hotel thief and he had made a very good living in this way. He has been arrested on many occasions and has had three felony convictions, and, being now on parole from State Prison, he has every inducement to avoid taking risks. But finding no other opportunity for employment, he became affiliated with a detective who made a practice of retrieving stolen jewelry by acting as a go-between between the insurance company who offered the reward and the thieves who abstracted the jewelry. The defendant was the contact man. He went to Palm Beach as part of his work and there got into difficulties with his former wife whom he had divorced. She caused his arrest and he was put out of town and so returned to New York. Here he had no occupation. He was walking through a hotel, happened to see a room door open; inevitably he stole something and is now finishing out his life in prison under the Baumes Law.

Here we have a type of behavior that is frequently met with. From a disorganized home the individual early indicates his dislike of routine work and becomes an "offender." Though a repeater, he tries to conform. But no matter how he rationalizes his behavior, he repeats his antisocial activities automatically and without any apparent predetermined plan.

Consider also this boy who is only seventeen. He comes from a good family in Massachusetts, his father being principal of a large high-school of the town in which the family lived. The boy showed many temper-tantrums in public school and was often in difficulties for striking his teachers. He has committed a series of larcenies of weapons in his native town without, however, being caught. Three years ago, he was arrested for "breaking and entering and larceny in the night time," and was sent to the Lyman School for Boys. Soon after leaving there, he was again arrested for "breaking and entering" and was again sent to the Lyman School. He escaped and was returned repeatedly. After his last escape, he came eventually to New York City. He was arrested here as he came out of a burlesque theatre because the butt of a revolver was seen protruding from his inside coat pocket. A quantity of jewelry was found in his possession that had been stolen in

another city. He gives the familiar misstatement that he "found the jewelry in a box-car" at the time when riding the "side-door Pullmans." He also claims to live in "jungles." The boy has the attitude and expression of the old-timer in spite of his youth and the presumable advantages of a good home environment.

Let us take another boy of favorable home conditions. This youth, now 21, has been becoming involved with the law off and on for the past five years. The son of well-to-do parents living in an excellent suburb of New York, he first got into difficulties by stealing a wallet from the locker room of the country club, at about the age of 15 or 16. Since then he has been sent to a fashionable military school and here he was requested to leave because he persisted in writing checks when he had no bank account. These were made good by an indulgent aunt. He returned to New York City but lived with this aunt who continued to over-indulge him. The boy is very wilful, spoiled. He is impulsive in spending money and very often when without funds writes a bad check which the aunt redeems. On a travelling trip in the South, he became involved with the law by walking out of a hotel without paying his bill and was recently arrested because he paid his hotel bill here in New York with a forged check. He was placed in the country on probation but did not like the circumstances and insisted on following his own way and coming to New York. He was returned to the simpler environment but it was not long before he got into difficulties through misuse of his employer's funds and he was finally sent to the reformatory. This youngster cannot put the consideration of his own temporary inconvenience above the threat of a prison sentence.

We see here again, in varied setting, the unmistakable repeater behavior, irrespective of age and environment. We see coincidently the automatic revolt against good behavior and the equally automatic return to so-called "bad" behavior. Also it is sufficient for the antisocial individual that *he wants* something—money, or watch or automobile—and he then forthwith appropriates it according to his wishes. He also evidences a persistence in his reaction type. There is, in general, a tendency for the individual to hold to one type of offense, though the more restless and more reckless individuals may progress into more and more aggressive crimes.

Many antisocial individuals have expressed to us, in one way or another, that they would rather run the risk and seek large amounts of money by illegal means than work regularly and laboriously for only moderate amounts. As they put it: "Why should I work all day for $20 a week, when I can go out and steal it in half an hour?" The hotel thief whose case has just been cited said, "You are used to getting money easy and lose the taste

for work. You get desperate when you are broke and do a crime." They express this in another way by saying, "Once you get hold of easy money you never want to take a regular job. It kills all interest in it." They dislike work, consider it a hardship and look upon it with pain.

These four individuals may be considered, then, as a fair sample of the cases of repeater-criminal that pass through our clinic. They are representative in general of the antisocial individual whose behavior may be characterized, as I have indicated, as being aggressive, competitive and indifferent to the welfare of others about them. Also, in accord with the findings of our clinic, this antisocial individual is exceedingly egocentric. And I should like in particular to call attention to the reaction, common among them, of placing a marked over-emphasis upon their own importance as individuals.

In this problem of the repeater criminal, that has so long puzzled the best of our students, lies a direct challenge to our civilization. As I have remarked elsewhere, the reactions common to the criminal are reactions that are common to mankind generally. In the behavior of the recidivist this observation is equally pertinent. We are confronted not so much by a problem that is isolated in the behavior of a special class of individuals as by a condition that exists throughout the race of man. Accordingly in our need for a broader approach to our problem we must establish a basis of observation that will encompass the generic factors that lead to antisocial behavior in mankind.

In this situation I cannot do better than refer to reports of Burrow's investigations of human behavior in which he states that we are confronted with precisely this problem in the attempt to cope with the underlying factors responsible for mental and nervous disorders. In his studies he found it essential to adopt a broad phyletic approach which considers each individual as an essential element in, an intrinsic member of, his race. For some years Burrow [10] has emphasized the fact—to take but one aspect of his thesis—that our social structure puts each individual through a very definite process of conditioning, a conditioning that is in direct opposition to in-

[10] Burrow, Trigant, "Social Basis of Consciousness," 1927, London, Kegan Paul, Trench Trubner & Co. Ltd.; New York, Harcourt Brace and Co., Inc. Pp. 50-55.

trinsic patterns of expression and of development. Broadly speaking the individual is conditioned almost from birth to believe that all actions, and even all thoughts are to be divided into the two categories, "good" and "bad." The child is constantly admonished to be "good," or to "do the right thing"; to avoid being "bad" or doing the "wrong" thing.[11] He is conditioned not merely by words but actually by tone, manner or general behavior to feel that "good" behavior will be approved and rewarded, and that "bad" behavior, namely that behavior which causes inconvenience to the parent or the admonisher, will result in disfavor and discomfiture.

At the same very early period of his life, each of us as an individual is conditioned to react with a special affective content to the stimulus word "you" or, as he himself feels it, "I," and the picture or image denoted by this word comes to have more importance than everything and everyone else in the world.[12] After constant re-emphasis by our social environment, this image of one's self becomes an artificial center about which all else rotates. "*You* did this," each of us is told as children, and "look out for *your* toy, or brother will get it." "Johnny Smith is a *good* boy, he behaves *better* than *you* do." "Work hard in school and be first in the class; *you* will get the prize."

We are thus conditioned to associate this idea of "good" and "bad," or "right" and "wrong," with the image "I" which each is given of himself. That which is "good" is to the advantage of this "I" and is to be sought, and that which is bad is to the disadvantage of the "I" and is to be avoided. Experiments in a group or social setting made in the laboratory of The Lifwynn Foundation[13] evidence the fact that every individual, normal or

[11] Burrow, Trigant, "Crime and The Social Reaction of Right and Wrong." Jour. of Criminal Law and Criminology, Vol. XXIV, No. 4, Nov.-Dec. 1933.

Galt, William, "Phyloanalysis, A Study in the Group or Phyletic Method of Behaviour-Analysis," Psyche Miniature Series, London, Kegan Paul, Trench, Trubner & Co., Ltd. 1933.

neurotic, great or small, is preoccupied with thoughts of himself and his advantage. It is obsessive with us. Each one becomes so conditioned that his thought automatically is "how will what is going on in this moment cause *me* gain or loss?" Normal individuals then are conditioned to a self-preoccupation—egocentricity—and to self-acquisitiveness.

This conditioning process early results in the isolation of each individual. This "I" is not the total organic personality, nor is the coincident "good" the basic need of organismic man. Accordingly, the criterion for what is good or bad is continually shifting. What is good in the eyes of one person may be bad in the eyes of another and *vice versa*. So that what we are trained to do is to present continually an *appearance* of doing what is held to be "good" or approved as conceived by the person or persons before us at the moment, or to give an appearance of feeling that fits in with the circumscribed opinion presented by the community, with its traditional thought patterns and prejudices.

By virtue of the image of himself which is thus secondarily acquired by the individual, and which differentiates him competitively from all others of his kind, an overemphasis is put upon the individual and in turn he is given an exaggerated sense of his own importance. He feels, though he naturally has no clear perspective on it, that his health or his ills, his likes and his dislikes, his gains or his losses are many times more important than those of his neighbor. Concomitant with this emphasis upon the supreme importance of each "I," each individual keeps secret this preoccupation with self-advantage and acquisition, and thus, in his feeling, others come to constitute competitors against him.

Any encroachment upon the assumed domain of this "I" by some other "I"—whether the domain be the individual's opinions, his "rights" or his sense of his importance—is met with a type of reaction that is characteristic the world over and is determined by the superficial nature of this authoritarian "I". Take, for example, such commonplace reactions to a fancied intrusion as petulance, irritation or anger, together with the various and equally superficial mechanisms of agreement for hiding the irritation—"tact" or "politeness" or "diplomacy"—that mark the behavior of man everywhere. Man quarrels, makes up and quarrels again, Since the reactions of groups show the characteristics of the re-

action of the individual,[14] including this conditioned subservience to the " I " image, this type of reaction is characteristic of man everywhere, in home, community or nation. The reaction is not only widespread and commonplace but, singly or in groups, man's behavior shows the same recurrent sequence. He repeats. His behavior is not merely automatic but the basis of his repetition is also the basis from which he attempts to observe his own behavior. Inevitably, his outlook is shortsighted and ill. Despite agreements, pacts, laws, peace-conferences, treaties, the ordinances of Church and the State, man quarrels, makes up and repeats, for this is the nature of human behavior where it has been conditioned to the superficial, self-acquisitive " I " image.

It should be kept in mind, then, that when we are confronted with a prisoner in our examining room, we are studying an individual who, like ourselves, is the resultant of this same continual conditioning process, for the criminal and the neurotic and the law-abiding citizens are all members of the same social structure or society, which, as we have described, automatically conditions all of its members to react affectively and disproportionately to this " I " image. However prevalent throughout society, man's affective response to this image or stimulus word " I " does not represent health or wholeness, for this " I " is a secondarily acquired image which has been inculcated in the individual and superimposed upon the organism's total personality. Though held in common by everyone, this image contrasts each individual with all others. It is the basis of man's self-preoccupation, of his oppositeness, his self-acquisitiveness or competitiveness; in other words, it is the basis of the personality traits which in their extreme form characterize the recidivist.

There is not time to go into the phyletic significance of internal tensional conflict which according to Burrow's investigations produces this conditioned behavior reaction in each individual throughout society.[15] It is sufficient for our purposes in the moment that this conditioned, separative " I " image represents a common denominator for the compulsive, egocentric acquisitiveness of man

[14] Burrow, Trigant, " Social Images Versus Reality ", Journal of Abnormal Psychology and Social Psychology, Vol. XIX, No. 3, Oct. Dec. 1924.

[15] Burrow, Trigant, " The Biological Basis of Conflict," New York, Macmillan & Co. 1937.

throughout the species, including the reaction of the non-criminals as well as the criminals. Civilization's outstanding characteristic and its fundamental anomaly is its systematic training of each individual to get for himself at the expense of others.

At this point the question may well be raised: how does a conditioning process that is universal in its scope, produce a special minority class of individuals whom we know as repeater criminals? We know that repetition is a characteristic of conditions of health; for example, the heart beat and respiration show a very definite characteristic of recurrence, and much of our living shows a very definite periodicity. We dress after much the same routine each morning, arrive at the office at about the same time each day, we meet people and carry on our work, each after his accustomed fashion, and this routine our associates come to know as characteristic of us. Things feel a little odd to us if we do differently. When we attempt definitely to alter our habitual ways of living and acting, we find it unexpectedly difficult. This is evidenced very clearly, to take but one example, in the proverbial frailty of our New Year's resolutions.

But beyond this, man's prevailing conditioning causes the individual organism to function within a configuration that, instead of being organismic and total, is circumscribed by the persistent superficial, autocratic and separative "I" image. In our superficial angers and hatreds or in our agreements, in our wars and in our equally superficial and evanescent arrangements called peace, "normal" man, like the criminal, is himself a repeater of pathological reactions. Naturally, then, if we are all involved automatically in repeated reflex reactions that have to do with oppositeness, self-acquisitiveness and competition, the nature of the behavior of the recidivist is not far to seek, for the problem of the recidivist is but the problem of man's behavior generally.

We might well keep in mind that society has its own crimes which, however, are not recognized as such because they are committed on so large a scale. Society has its mass-homicides called wars, its mass-robberies called invasions, its wholesale larcencies called empire-building. As long as the individual's behavior fits in with the mass-reaction it is considered "good" behavior. As long as he does not question by word or deed the validity of the mass-behavior he may be called a "good citizen."

With all of us law-abiding folk, our familiar pattern of behavior conforms to society's accepted but thoroughly inconsistent and artificial behavior code. It *feels better* to us to continue to live within the law. It is not because of any superior outlay of effort on our part that this is so, but rather because it fits in more with our comfort; this type of behavior is, in fact, automatic—and repetitious—with us. The "antisocial" individuals, however, are those who happen to balk at society's quite artificial though commonly accepted code. The advantages which society promises in return for "good" behavior do not appeal to them as in any way making up for the onerousness of monotonous toil which this program entails; or in certain cases, their aggressiveness may fall outside the mass behavior-pattern. Early in life they find the delimitations of conformity disagreeable or impossible; their reaction pattern is persistent in that special category of behavior that society calls "bad." They react automatically, just as we do, but their habitual reaction happens to be in a proscribed field; hence their particular form of repetition makes them "repeater criminals."

Whenever the repeater is able to put his feeling into words, it is to express a justifiable defense of his action—his right—since he feels that what he has done is in accordance with his own standards and rights. For the most part, even with the intelligent offenders, their behavior is automatic—because it is reflex—whether in revolting against a normal job, or in perpetrating an unlawful job. They act automatically as a direct symptom of society as a whole. In this broader setting, the egocentricity of the overtly antisocial or criminal individual appears in a different perspective. Criminals present merely an exaggerated form of the ego-preoccupation that characterizes the individuals of our "normal" society, and, in our attempt to deal with them, we are confronted with a problem in community behavior.

In the absence of a clear accounting of this community problem, we can only expect the supply of antisocial individuals to continue to pour into our courts and prisons; and we cannot hope that our present legal and correctional procedure will fundamentally alter the behavior reaction of the individuals whom we have called repeater criminals. Our responsibility, then, is to reckon broadly with those factors within ourselves which determine antisocial trends throughout society and of which the behavior of the recidivist is but one aspect.

MENTAL CHANGES FOLLOWING THE REMOVAL OF THE RIGHT CEREBRAL HEMISPHERE FOR BRAIN TUMOR.*

By STUART N. ROWE, M. D.,† Pittsburgh, Pa.

During the past few years with the improvement of technical methods in neurosurgery, and with the development of increasing hardihood on the part of neurosurgeons, and perhaps their patients, a few cases of very extensive cerebral ablation for brain tumor have been reported. Since the postoperative study of these patients may add to our knowledge of mental and neurological mechanisms, and since such cases are still not common, it seems quite proper to record them. In the present report, interest is centered particularly upon the effects on the mental status of the patient of the removal of a fairly large amount of cerebral tissue.

CASE REPORT.

E. B., white female, aged 38. Hospital No. 5749.

Summary.—Headaches and the roentgenologic finding of calcification in the right frontal region led to the partial removal of a right frontal astrocytoma in January, 1935. Symptoms of increased intracranial pressure, epilepsy and mild mental changes appeared about six months later; and one year after the first operation a second more radical removal of the tumor was carried out. Ten months later (December, 1936), because of headaches and mental changes, a third operation was performed and most of the right cerebral hemisphere was removed. When examined six months after operation, the patient showed moderated emotional instability, slight impairment of recent memory, slight diminution in the normal inhibitions, but little, if any, deterioration in her intellectual ability as measured by mental tests.

Present Illness.—The patient was first seen in January, 1935. At that time she gave a history of progressive, severe headaches for about one and one-half years. Examination showed only a very slight weakness of the left corner of the mouth, and a mild euphoria. X-rays demonstrated extensive calcification in the right frontal region.

First Operation.—January 31, 1935, a right transfrontal craniotomy and partial removal of a right frontal astrocytoma was carried out by Dr. Charles H. Frazier. A decompression was provided.

† From The Neurosurgical Service, Landon Surgical Clinic, The Western Pennsylvania Hospital, Pittsburgh, Pennsylvania.

Course After First Operation.—For four months the patient was symptom free. Headaches, petit mal and grand mal epileptic seizures, and more pronounced euphoria then slowly developed. Examination in February, 1936 (one year after the operation), showed some swelling of the right subtemporal decompression, slight haziness of the borders of the optic discs, marked impairment of the sense of smell on the right, hyperactive tendon reflexes in the left arm, and slight weakness of the left corner of the mouth and left arm. Mentally the patient was mildly abnormal in that she was markedly loquacious, excessively cheerful, and even jocose at times. Her intellectual ability on the Stanford-Binet scale was that of a superior adult with an intelligence quotient of 115.

Second Operation.—February 7, 1936, a craniotomy was carried out (by the author) and about two-thirds of the tumor removed before the patient's reaction became so severe that the operation had to be terminated. The mass of tissue removed measured 6 x 6 x 3 cm.

Course After Second Operation.—Complete relief of symptoms was experienced for about six months. The immediate improvement in the patient's psychic state was marked. She became more calm, less talkative and jocose. On a repetition of the psychometric examination, she improved slightly upon her previous score.

About seven months after the operation, however, bouts of severe headache, and more pronounced mental changes began to appear. At times she was greatly depressed about her condition and would discuss various methods of suicide in a half-serious and half-jocose manner. On several occasions she reviewed her various symptoms and problems and future outlook at some length and with the utmost frankness on rather unusual occasions—such as in the course of a telephone conversation with a casual acquaintance, and at a bridge party. She was greatly worried over the prospect of further surgical treatment, but was equally distressed when she contemplated continuing life in her present condition. The over-talkativeness and lack of inhibition grew steadily worse. Nevertheless, the patient's sensorium and general intellectual resources remained fairly normal, although she complained of difficulty in remembering names and dates and even occasionally recent events.

After a discussion with the patient and her family of the risks and possible sequelæ of a third and more radical attack upon the tumor, operation was once more decided upon.

Third Operation.—December 7, 1936. To provide a wider exposure, a small additional bone flap was reflected posterior to the original one. The tumor was found to lie principally in the frontal and temporal lobes and an effort was made to remove these areas without injuring the motor cortex, but tumor was encountered extending subcortically back into the parietal lobe. Accordingly, this procedure was abandoned, and the entire right hemisphere with the exception of the basal ganglia and a small medial portion of the temporal lobe was removed. In the frontal portion of the tissue remaining, there was some suggestion of tumor infiltration. This was removed as widely as seemed possible without encroaching dangerously upon the basal ganglia. (Fig. 1.)

Course After Third Operation.—The cavity, filled with bloody spinal fluid, was aspirated daily. During the second and third post-operative weeks a staphylococcus infection occurred in this fluid, but the patient recovered with no change in therapy other than repeated aspiration and a transfusion. Her convalescence was also slowed by a low-grade osteomyelitis which developed in the small bone flap and necessitated its removal eight weeks after the operation.

The patient was completely hemiplegic on the left side for about seven weeks. At that time she began to make efforts to walk, with support on both sides, and discovered that she was obtaining a return of motor power in the left leg. This improved slowly and with the aid of a brace to support the left knee and ankle, she could walk with only slight aid ten weeks after operation. Touch sensation was lost on the left as well as two-point discrimination, sterognosis, sense of position, sense of motion and vibration, but pain sensation was preserved to some extent in scattered areas and was fairly well localized. The patient showed some limitation of conjugate eye movements to the left and upward for about eight weeks, and had of course a left homonymous hemianopsia (which spared the macula). The hearing was normal on both sides to ordinary testing (watch, whispered voice).

For a number of weeks after operation, the patient's mental state was considerably influenced by a number of changing factors—the operative shock, the blood in her cerebrospinal fluid, changing intracranial pressure, the post-operative infection, the prolonged hospitalization—and was correspondingly variable and difficult to evaluate. For the sake of completeness, however, this period may be briefly reviewed.

The patient showed marked lack of normal inhibitions for some weeks. She was highly euphoric at times, joking excessively, and sometimes very wittily, and always talking with very little restraint. Her mood varied widely and rapidly from time to time and she was occasionally extremely despondent. Her thought content was largely limited to her own situation for a time. The events since operation were poorly recalled, if at all, although older events and even such items as addresses and phone numbers were accurately remembered.

In the course of three or four weeks the patient's reactions became much more normal. While still displaying some lack of restraint in her speech, her inhibitions improved so much that her behavior and conversation were more natural than they had been prior to the operation. Her stream of talk was much less active and her restlessness decreased. The patient's emotional control, though improved, continued to be inadequate (presumably on the basis of operative trauma to the basal ganglia, or their injury in the course of the infection). She occasionally lost control of her voice or broke into sobs, though these outbreaks almost always accompanied a depressing thought content and were not altogether illogical or involuntary. Her outlook broadened so that she took a normal interest in her personal appearance, her home and family, her friends, and the activities of the world at large as portrayed in the daily papers.

Present Neurological Status.—Six months after operation. The cranial nerves are entirely normal with the exception of the left homonymous hemianopsia. The patient is only able to raise the left arm about six inches from her lap, but as the result of considerable physiotherapy the extremity is only moderately spastic and shows no contractures. The power in the left leg is about 75 per cent of normal on individual movements, but with the aid of a brace, the patient walks about the house by herself quite comfortably. The sensory changes are essentially the same as at the previous examinations—pain sense being preserved in irregular areas and being fairly well localized.

Present Mental Status.—

1. General appearance and behavior. The patient is quite particular about her personal appearance, is neat in her dress and toilet. She remains at ease and cooperates well throughout the examination. There are no special mannerisms. (Fig. 2.)

2. Stream of talk and activity. The patient's physical activity is still considerably limited by her hemiparesis. She is out of bed about 12 hours daily, walks about the house freely, spends some time on a small terrace out of doors, and goes for a daily walk or ride in the car. She can walk three to four blocks with slight aid from one person without excessive fatigue. In general she fatigues more easily than formerly, but manages to carry out the above program with little difficulty.

Mentally the patient is quite active. She is in charge of the management of the household (6 members), plans the meals, directs the cleaning, the buying, etc. She spends several hours daily working with her daughters on their school work and is normally worried over the failure of the younger (whose achievements in school are only average) to keep up with her sister (who does superior work). She takes a keen interest in the current events of her neighborhood, the happenings recorded in the newspapers, and reads several popular magazines fairly completely. Her retention of what she reads is sufficient to permit her to enjoy a continued story in a monthly magazine, but she has taken relatively little interest in books as yet. Rather frequent callers at the house occupy much of the patient's time, and with them she converses at some length, with some tendency to loquacity and to dominate the conversation. She maintains an active interest in her neurological and mental progress, as well as in the physiotherapy which she receives three times weekly.*

3. Mood. Emotionally the patient is still somewhat unstable. At times she becomes depressed very easily about her condition, and perhaps once in 24 hours she may weep without any real cause. When her attention is occupied with other matters than herself, she maintains a very even, cheerful mood.

---

* The patient received physiotherapy for six months under the direction of Dr. J. M. King. This prolonged and careful treatment certainly contributed much to the recovery of motor power by the patient.

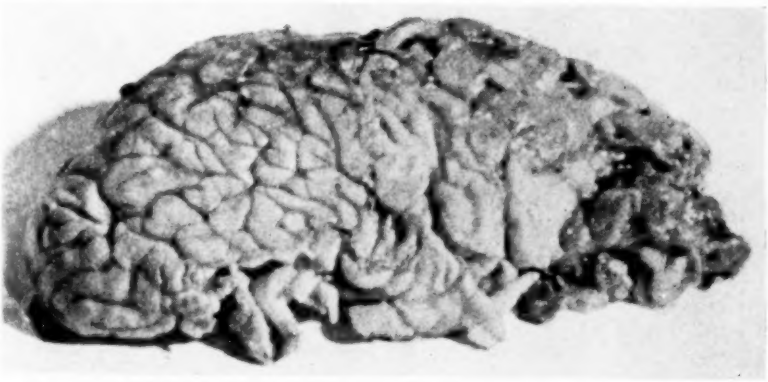

FIG. 1.—Specimen removed at operation. The tumor presented on the surface anteriorly and infiltrated the parietal lobe subcortically.

FIG. 2.—The patient six months after operation.

UNIV. OF MICH.

4. Thought content. So far as can be determined, the patient has no abnormalities of her thought content. No compulsions, delusions or hallucinations have occurred at any time since operation.

5. Sensorium and intellectual resources. The patient is well oriented in all spheres. Her ability to concentrate in carrying out a test seems about average, but in the course of ordinary conversation she tends to shift fairly rapidly from subject to subject.

Some difficulty in recalling events of several days or weeks previous is at times experienced by the patient, but on testing recent memory and immediate recall there is no deficiency.

As measured by the Stanford-Binet tests, she still is in the superior adult group, with an intelligence quotient essentially the same as that found on the examination one year before.

6. Insight. The patient is aware of her emotional instability, and of the occasional memory difficulties, and is constantly trying to overcome them.

Finally, it seems worth emphasizing that the patient's mental status is still changing—at present improving. What progress or regressions may occur in the future is, of course, unpredictable.*

COMMENT.

In this patient, the only mental changes six months after removal of most of the right hemisphere were (1) mild loss of normal inhibitions with a tendency to over-activity of speech, (2) some impairment of recent memory, and (3) moderate emotional instability.

Unless one assumes a very extreme dominance of the left cerebral hemisphere in man these changes seem astonishingly mild after such severe cerebral insult. A brief review of previous experimental and clinical studies however, makes them seem more plausible. It is true that Lashley,[1] in his elaborate studies with rats found that loss of learning ability following injury to the brain occurrred in direct proportion to the mass of cerebral tissue destroyed, without regard to the location of the lesion. But the careful work of Fulton, Jacobsen and their associates, [2, 3, 4] with chim-

* Eight months after operation the patient has made some further gains. The strength in her left leg has improved sufficiently to enable her to discard the brace and still get about the house easily and take a short walk daily. The patient's mental attitude is considerably improved. She is quite optimistic and cheerful and has a far better emotional control, so that the outbursts of weeping which formerly troubled her, now occur very rarely. She has begun to read books with more enjoyment and seems to have less difficulty with her memory.

panzees and monkeys showed that in the primates unilateral frontal lobe lesions have little if any effect upon the higher mental processes, while bilateral frontal lobectomy caused a profound change—particularly upon mental activities demanding integration over a period of time. Furthermore, in these animals cortical ablations of equal or greater size (even when bilateral) which did not involve both frontal lobes failed to produce a similar mental picture. No evidence of dominance of either hemisphere was found.

The rather meager data as yet available from human cases tend to coincide with those obtained by these latter studies. A few cases of extensive unilateral cerebral ablation have been reported. Dandy [5] has recorded five cases of hemispherectomy for brain tumor. Three of these patients died within relatively short periods so that no estimate of their postoperative mental states could be obtained. One patient lived three and one-half years before dying of a recurrence of his tumor. Of him Dandy wrote, "There did not seem to be any obvious mental impairment. He was always happy and grateful for his extension of life." The fifth patient was described two months after operation as rational at all times, well-oriented, having a good sense of humor, and seeming normal mentally. The patient reported by O'Brien [6, 8] and by Gardner,[7] who lived five years after hemispherectomy, was said to have shown no mental abnormalities whatsoever, although no exact studies of her intellectual level before or after operation were carried out.

In addition several studies of bilateral frontal lobe lesions are available. Ackerly [9] studied carefully the psychic changes in a case operated upon by Spurling—a woman whose left frontal lobe was severely compressed by a large mid-line meningioma, and whose right frontal lobe was removed to permit the extirpation of the lesion. In this case, two years after operation there was no significant diminution in intelligence, no disturbance in the emotions or in general behavior, except a certain lack of distractibility, or tendency to an increased concentration upon the task at hand. It is not known of course, how much function may have returned in the injured frontal lobe following the removal of the tumor. One reason for suspecting the return of function on the left is the report of much more incapacitating mental deterioration in the case studied by Brickner.[10] This patient, both of whose frontal lobes

were removed by Dandy, showed as his fundamental defect a quantitative diminution in the ability to synthesize—which in turn led to considerable loss of intellectual power and great alteration of the personality.

Finally, the operations carried out by Moniz [11, 12] and by Freeman and Watts,[13, 14] for the relief of certain abnormal mental states involve the bilateral destruction of varying amounts of frontal lobe white matter. The procedure is reported to have greatly improved the psychotic states (particularly agitated depressions), without any marked change in the intellectual level, and with only occasional transitory effects on other mental functions. It is of considerable interest that these relatively small bilateral frontal lesions should produce such marked psychic alterations.

In summary, it would seem that the evidence available at present suggests that the higher cerebral functions in man are less dependent upon the integrity of the cortex as a whole than upon the preservation of the frontal lobes—a conclusion which is supported by the effects of hemispherectomy in the case here reported.

SUMMARY.

1. A case of removal of the right cerebral hemisphere for brain tumor is reported.

2. From a neurological standpoint, the return of considerable motor function and some sensory function on the opposite side of the body is of interest.

3. Mental changes including impairment of recent memory, emotional instability and diminution in the normal inhibitions, are present six months after the operation, but the patient's intellectual resources, personality and ability to meet the demands of her daily life have not been greatly altered.

4. The relatively mild mental changes resulting from hemispherectomy in this case are in keeping with previous experimental and clinical studies which indicate that in primates and man the higher cerebral functions are more severely altered by bilateral frontal lobe injury than by corresponding or even more extensive lesions of any other areas.

DISCUSSION.

DR. LLOYD J. THOMPSON (New Haven, Conn.).—A point more or less covered by Dr. Alford, was that we really don't know the condition remaining. We have a rather discreet removal of brain tissue here, but there is a possibility that what is left is not quite normal as yet. Maybe it will be sometime, but when we think of the pressure, the edema, and the infection that has occurred, there is a possibility that the other hemisphere, and perhaps the basal ganglia, may have suffered in some way.

I bring out that point because these mild personality changes that have been noted may be those that are seen in bilateral frontal lobe conditions,

and in time perhaps they will disappear, as in Ackley's case. Perhaps later we will have evidence that the unilateral removal of the frontal lobe and of the one hemisphere may really be as the clinical reports and the experimental work has intimated that the person can do very well without that side of the brain.

I don't know what Dr. Rowe's plans are for the future in studying this case, but I hope that my suggestions will be of help. In a case as important as this, there should be a combined effort on the part of neurologists, psychiatrists and psychologists. Dr. Rowe pointed out that some of the important cases of the past had missed being studied in the proper way afterwards. I don't think any one man can look into all these fields as well as they should be, and that is a suggestion that I make.

The routine mental status as we examine in cases of psychoses, and the ordinary intellectual intelligence tests are not enough, and I think that psychiatrists and psychologists and neurologists can go quite a way in bringing into a study of this sort more refined techniques and a broader point of view than has ever been used in the past.

A psychiatrist, of course, is interested in the patient like this from the standpoint of the whole individual and his adjustment to his environment and his culture. We can analyze the personality, breaking it up into a study of the impulse life, what is happening to that, temperament, and in that particular field we see evidence in these lobectomy cases that something does happen in that particular field. Then we could go on and study the character of the field.

Put in different terms, and looked at in a different way, I think our psychoanalytic colleagues would be interested in a case of this sort to see what happens to the id, the ego, and the super ego. We picture the super ego as up there in the cortex, and from a psychoanalytic point of view it would be interesting to see if any light can be thrown on it.

There is one symptom in which I am particularly interested, it occurs in these cases as well as others, and that is the hyperkinesis, this overactivity that occurs in reported cases of lobectomies and various other discreet removal of brain tissue, post-encephalitic cases, tumors, and so on. Some light might be thrown on that particular symptom from a careful study of a case of this sort. That patient did show it occasionally from time to time, I believe, but it seems to be quieting down.

I suppose the question is the release of the basal ganglia from cortical inhibition, but I am under the impression it is a much more complicated thing than that. From the standpoint of psychology, I am sure the ingenious clinical psychologist can help in organic brain cases, and particularly in these cases.

There was mention of the memory being preserved in Pick's disease. With the aid of Dr. Miles, our psychologist, we were able to show quite definitely that although clinically to us the patient looked to be definitely failing in memory, there was a much greater memory retention than appeared to the clinical observer, but the use of that intelligence as an intellectual tool was impaired.

The synthesizing of the intellectual functions can be elaborated to quite an extent by the clinical psychologist.

The question of cortical dominance in a case like this is of tremendous interest. If this patient happened to have been, let us say, left-eyed and right-handed, a study of the combinations that you might get out of that would be interesting. It could help, probably, in the work that Dr. Orton is doing.

Then there is one other psychological thing which is psychiatric, and that is the Ronchese test. It would be interesting to see what that shows. I have had the opportunity of observing Dr. German's cases, and I have seen a good many of Dr. Fulton's monkeys, and I agree with the general impression that Dr. Rowe gets here, that unilateral lobectomy doesn't do much damage to the total personality.

I don't think we can say that there is any one psychological symptom that is characteristic of frontal lobe or unilateral hemisphere function, and I don't think we can say there is any one clinical picture that is characteristic of disease of one side, or of removal of one side.

Holmes has pointed out that there are several clinical pictures that may come with such involvement, and I think it depends a lot on the personality, and that means that we study the original personality.

One more point is that in the description of cases similar to Dr. Rowe's, whether it was unilateral or bilateral removal, that we don't seem to get a picture resembling schizophrenia. We get pictures resembling all sorts of other things, but nothing that gives a clear-cut picture of a schizophrenia. That makes us stop and think whether we will ever find the answer to schizophrenia in definite brain pathology.

Dr. Stuart N. Rowe (Western Pennsylvania Hospital, Pittsburgh, Pa.).—I thank Dr. Thompson for the discussion, and particularly for his suggestions as to the further study of the patient.

I have already enlisted the aid of the psychologist. I won't say I have gotten as far as the psychoanalyst, but since the patient has survived at the hands of the neurosurgeon, I think she would be willing to face any further tests of the psychoanalyst.

DEFECTS OF INTELLIGENCE FROM FOCAL LESIONS WITHIN THE CENTRAL PART OF THE LEFT CEREBRAL HEMISPHERE.

By LELAND B. ALFORD, M. D., St. Louis, Mo.

Thirty years ago Pierre Marie [1] in communicating the theory of aphasia, to which his name is attached, expressed the view that a defect of intellectual functioning is produced by lesions within a certain area (roughly posterior central in location) of the left hemisphere in right-handed persons. Many clinicians doubtless have observed that apparently without any constant relation to the extent and severity of the lesion or even the degree of aphasia, cases of right hemiplegia exhibit a wide variation in the extent of the accompanying intellectual involvement. Apparently, therefore, certain parts of the hemisphere are more particularly concerned with the intellectual functions than are other parts. Since recent contributions of brain surgery have served to throw a new light on the whole subject and incidentally have disclosed new avenues of investigation and since the implications of Marie's contribution are obviously both broad and important, the present writer decided several years ago to make further studies along the line indicated.

The points under investigation, consequently, have been the occurrence or not of intellectual defects with focal lesions, the nature of the defects and the location of the respective lesions. Although the evidence presented is not in all respects complete and conclusive, it now appears that the point made by Marie was well taken and eminently worthy of further development.

Psychiatrists are familiar with such pictures of intellectual disturbance, produced by diffuse processes, as are represented by the terms " dementia," " confusion " and " clouding of consciousness." Further the phrases which neurologists employ in connection with aphasia like " loss of inner speech," " agnosia " and " semantic " defect also imply intellectual disturbances, but of a limited and specialized kind. The former offer the analogies which are useful in the present relation, the latter being of interest chiefly as com-

plications that occasionally must be discounted in judging underlying mental states.

The criterion adopted for deciding about the involvement of mental functioning was therefore the composite clinical picture of clouding, confusion and disturbance of memory. It would be possible to resort to the quibble that any limitation of attention, memory, or initiative constitutes a defect, but such changes are far from being the generally *abrupt* and *distinct* changes that constitute defect in the accepted sense.

A point to be kept in mind in this connection is the decisive value of negative over positive findings. *It is no exaggeration to assert that many observations in this field, for instance those recording the mental changes accompanying tumors, are misleading because of failure to recognize this fact.* Transmitted pressure, circulatory changes, edema and other physical alterations in the intracranial status, as Dandy rightly observes, can affect functions surprisingly at a distance from the lesion itself; but in the absence of a mistake as to handedness or an anomaly the negative finding is conclusive. Some have found it difficult to accept Dandy's negative findings following massive excisions, but the writer has experienced no such skepticism for the reason that after weighing positive against negative evidence in a series of cases, he had already arrived at similar conclusions on several of the points. One can only be reasonably safe in accepting positive findings when the lesion is limited in size, destructive in nature and has been in existence for some days.

In these present studies, further, due regard has been given to complicating factors, such as aphasia, apraxia, shock, weakened condition and general arterial change. The difference between willed and impulsive responses often referred to in the literature of aphasia likewise has proved to be an extremely important one, the latter doubtless being the more accurate as an index when patients are apraxic or easily confused (see Cases 2 and 4 below). After gaining experience one becomes able to recognize and discount these interfering features in reaching conclusions about the degree of defect in situations that are not always simple.

Negative Evidence from the Literature.

Dandy's [2] original conclusions are so cryptic that they can appropriately be quoted *in toto:*

(1) It is possible to remove all of the right cerebral hemisphere above the basal ganglia with no appreciable disturbance of mentality; this procedure has been carried out on several occasions for the removal of extensive tumors in the right hemisphere.

On one occasion both frontal lobes have been completley extirpated for the treatment of a bilateral frontal brain tumor and following this there has been no appreciable disturbance of mentality. The patient is perfectly oriented as to time, place and person; the memory is unimpaired; he reads, writes and conducts mathematical tests accurately; his conversation is seemingly perfectly normal.

(2) Furthermore by the excision in other cases of the left occipital lobe and of the lower third of the left temporal lobe, we can be sure that none of these regions are responsible for intelligence. The intellect, therefore, is concerned with the remaining portion of the cerebral hemisphere and is doubtless closely related to the speech mechanism.

(3) It has been found after ligation of the anterior cerebral artery on the left side that consciousness is completely and forever lost. This does not result when the same vessel is ligated on the right side. There is, therefore, within the limits of distribution of this vessel an area specifically concerned with consciousness. The same result follows when this vessel is occluded at the middle of the corpus callosum, indicating that the seat of consciousness is posterior to this point in the vessel.

(4) The entire body of the corpus callosum may be split in the midline without any appreciable disturbance of function. This structure is, therefore, eliminated from participation in the important functions which have hitherto been ascribed to it.

Dandy [3] also states that no disturbance of "consciousness" or other essential mental defect was observed after excisions of the whole of the left temporal lobe, the occipital lobes, either or both, or (apparently) the left occipital lobe, the supramarginal and angular gyri (in large part) and a part of the temporal lobe posteriorly (the incision being "vertical and slightly behind the postcentral gyrus"); although he encountered the complications of temporary anomia in the first instance and permanent visual aphasia and agraphia in the last. Thus Dandy's excisions gave negative findings as regards mental defect after the whole of the right hemisphere down to the basal ganglia and optic thalamus and all regions of the left hemisphere excepting that under consideration in the present discussion had been excised.

Dandy's assertions have received noteworthy corroboration as follows: In O'Brien's and Gardiner's case [4, 5] the entire right hemisphere was removed down to the central gray masses and the patient survived for almost five years. It is stated that relatives and friends could detect "no alteration in personality or intellectual abilities" and that "her memory for recent and remote events was good and she read constantly." To be brief, the patient appeared to expert observers and to her family and friends to be normal and unchanged mentally and emotionally except for an occasional slight apathy.

Other confirmation comes from Penfield and Evans [6] who report on the removal of the frontal lobes. After one large left frontal removal, in which the incision crossed Broca's area, there was no residual speech defect and mentality was preserved except as to the minor details of the ability to do mental arithmetic and to play bridge and perhaps as to initiative. A smaller left frontal excision was similarly negative. These workers, as well as Dandy, place the functional part of Broca's area somewhat farther back than is usually done.

It will be observed that excision of the right hemisphere does not take into account the great central nuclei—the lenticular and caudate nuclei and the thalamus—and immediately adjacent structures. The writer [7] attempted in 1933 to investigate these structures through the medium of left hemiplegias of vascular origin wherein the lesions, according to statistics, are likely to be located among these structures in a large majority of instances. Fifty cases taken at random from material at an infirmary were all negative for intellectual involvement, while 50 control cases of right hemiplegia yielded a very different result. Numerous observations since that time have disclosed that it is rather rare to find mental defect with left hemiplegia. Hence the entire right half of the brain from cortex to base can be eliminated as the primary source of basic mental defect.

These negative results, which, as has been explained, are highly conclusive, have narrowed the space where lesions will affect fundamental mentality down to that now under investigation. One cannot fail to admire Marie's clevereness in so exactly delimiting with the limited resources at his command the significant area of the brain.

The problem is now confined to the investigation of the effects of lesions within this remaining area—an extremely convenient limitation.

Clinical Studies of Cases of Vascular Accidents.

It occurred to the writer that now that the part of the brain to be studied was confined to the middle portion of the left hemisphere, the vascular accident with right hemiplegia afforded a useful source of material. The lesions in this condition were known usually to be situated within this area, often to be limited in extent and, as indicated by the variations in symptomatology, to vary somewhat in location. The destructive lesion, it seemed further, should present a minimum of pressure and circulatory effects on surrounding structures, especially after the lapse of some days. Accordingly material of this nature has constituted the chief source of data.

A review of the clinical findings may be presented in summary form as follows:

(1) Hemiplegia is seen without aphasia or mental involvement of noteworthy degree. This occurs in perhaps a third of the cases, a great majority of which undoubtedly belong in the right-handed group. One instance of this kind may be mentioned:

> The patient, a man of 48, with myocarditis, suffered right hemiplegia of gradual onset that became almost complete. On not a single day did the patient fail to attend to some business matter. He went through a period of several months of mild emotionalism and for a year was rather excitable and easily fatigued. Now, two years later, he is putting in a full day of very responsible work as the head of a large institution, although there is still almost no movement in the hand and foot and movements of proximal parts of the arm and leg are very limited.

(2) Sensory disturbance of the affected side was encountered in only two instances when mentality was unaffected. This fact perhaps indicates a spatial relationship between the sensory and psychic structures in the brain and therefore constitutes an aid to localization.

(3) Emotional disturbances occur both in the presence and in the absence of intellectual defect. Excitement and restlessness are not uncommon during the stage of shock from severe lesions of acute onset and also sometimes occur with defect of intelligence when shock does not appear to be a marked factor.

Forced or facile weeping is rather common in association with the milder forms of intellectual defect and perhaps is observed also when the defect is very slight or absent. An especially interesting observation was the occurrence in the absence of much or any defect of a state closely resembling the depressed phase of manic-depressive psychosis, that lasts several weeks or months and then passes. These emotional disorders were taken to be aspects of the thalamic emotional syndrome.

(4) The matter of the interrelation of intellectual and speech defects has a bearing on the important theoretical question of whether the two are inextricably combined or are distinct affections. Mixtures of the two are certainly common and difficult, but after some experience, not impossible to evaluate as to the relative entrance of the one and the other factor. It is, however, on the individual case which is less complex that we have to rely in deciding the question mentioned.

It has long been stated that the so-called sub-cortical asphasia is a type of motor speech disturbance in which the intellect remains almost, if not completely, normal (see Case 2, below). Recently Kennedy and Wolf [8] in a very interesting and instructive article have affirmed, after detailed studies, the validity of this statement. Jargon aphasia, too, as indicated by Case 4, below, may be accompanied by but slight basic intellectual defect.

The converse of this situation, namely the existence of intellectual involvement in the absence of aphasia, is even more difficult to establish; for one reason, because when the defect is at all marked speech becomes limited and utterance is apt to be indistinct. But if one is willing to accept relevant answers to a number of questions as showing the essential absence of aphasia, then certainly defect not rarely occurs with little or no aphasia. On this point Dandy asserts: [3] "Moreover many patients with central lesions talk and understand speech perfectly, but the mind is badly affected" (p. 56).

The indication, therefore, is that speech and intellectual defects are, at least in large part, separate and separable affections.

(5) The depth and nature of the defect are obviously problems of importance, but as further studies on this subject are contemplated, it will not be considered in detail here. It may be said, however, that certain difficulties attend such a study, among which are,

first, the tendency of patients with much defect to succumb early, even before the stage of shock is probably past; and, second, the continuous improvement which the intellectual defect like the hemiplegia often undergoes. It is still a question whether the more profound and permanent defects are not the result of multiple lesions; nevertheless there is little doubt that defects of all lesser degrees from focal lesions can persist indefinitely.

The character of the defect varies so much from patient to patient that it can almost be said that each case is a law unto itself. Dullness, clouding, confusion and stupor, as these terms were understood, as well as states not easily defined, are encountered in all degrees and combinations. (Memory loss is no absolute index to the degree of involvement, as might be expected.) The obvious conclusion would be that what we call intellectual defect is made up of several elements; although these elements would be of a similar order in their bearing on mental functioning.

To summarize, defects from focal lesions occur and can persist in all degrees up to the most profound; and defects as encountered are probably made up of a number of related elements.

From these clinical observations, therefore, it appears that hemiplegia occurs without speech or mental defect, but that sensory disturbance in such circumstances is rare; that emotional upsets, probably of thalamic origin, are encountered both with and without defect of intelligence; that motor and probably also jargon aphasia can exist without much or any intellectual disturbance and that, conversely, a high degree of intellectual impairment occurs in the absence of marked aphasia; and that the defects themselves, although conforming in general to the type known to psychiatrists, are both variable and difficult to evaluate and probably are composites made up of a number of related elements.

A general conclusion, therefore, is that the intellectual defect occurs in certain, but not all, cases of hemiplegia and of aphasia and that defect from focal lesions comprises, at least in part, a separate and distinct disturbance or group of disturbances. These clinical observations on numbers of cases, although in the absence of post mortem examinations to be viewed with caution, still serve to delimit and to clarify conceptions of essential intellectual defects.

Clinical and Pathological Studies of Cases of Right Hemiplegia.

Case 1.—*Large lesion that cuts off the cortex of the parieto-central lobe, leaving the great nuclei as the only functioning structures of the area under consideration. The patient very unresponsive, but facial expression maintained and a few quite complex mental responses carried out.* (Figs. 1 and 2.)

The patient, a vigorous 58-year-old professional man was stricken with a right hemiparesis that did not become complete for six days. The general condition, except for occasional spells of weakness, was good up to three days before the end. Aphasia was complete from the start. Duration of illness, 14 days.

The mental state was practically the same throughout. The patient's facial expression of alertness was maintained and the eyes moved automatically, at first glance giving the impression of actual fixation. The unaffected hand alternately rested upon, smoothed or drummed on the bed covers, touched the head or otherwise employed itself as if purposefully. Whenever the patient was embraced by a close friend, the hand rested naturally upon and gently patted the other's back. A light flashed into the eyes caused no winking and no fixation and pin pricks and loud comments seemed to provoke no response at all. Yet the patient frequently pulled out the nasal tube and a dose of salts was spewed forth violently with an expression of extreme disgust. Potassium iodide was also refused. The demeanor as a whole suggested an absent-minded or abstracted mood. Observers differed widely as to the degree of understanding retained.

In the midst of this generally unresponsive state, however, occurred a few mental responses of some complexity. The patient regularly took fluids through a tube when asked to do so; and when the time came to turn him in bed, he would, to command, assist so effectively that one nurse was able to complete the operation. When one grasped the hand in a handshake and asked the patient to reciprocate, there was a gentle return pressure and then the fingers toyed absently with one's hand. Finally when close friends greeted him, a greater animation seemed to be displayed than when the person was less well known.

This case probably corresponds to the two of Dandy in which the frontal artery was ligated,[3] the different picture probably being assignable to the difference in rate of onset. Certainly there was not the complete and permanent unconscious condition which Dandy describes in his cases. Apparently the patient retained a good deal of mental functioning, since the responses indicated some activity of the faculties of hearing, comprehension, kinæsthetic sensibility and motor coordination, and this despite the fact that the large and recent lesion nearby must have markedly dampened all such activities. As a large part, if not all, of the parietal cortex was directly

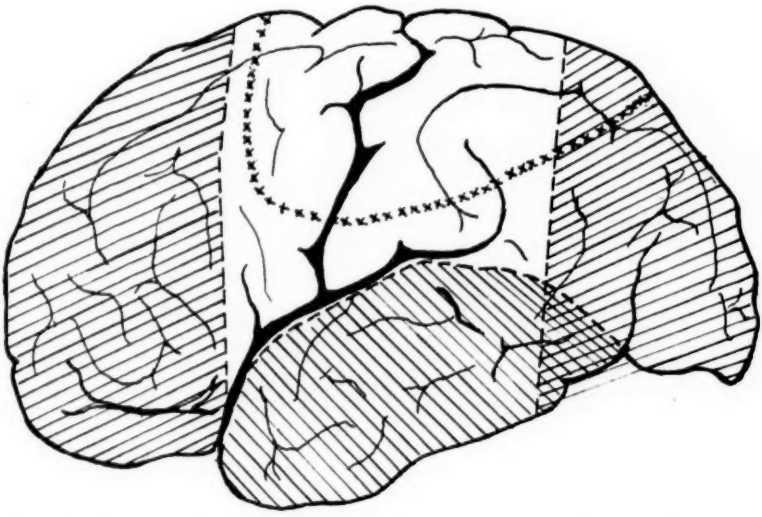

FIG. 1.—Drawing taken from Dandy.[3] The shaded areas represent different surgical excisions. The unshaded area and underlying parts are therefore the structures under investigation. The line of crosses has been added to indicate the projection on the surface of the limits of the lesion in Case 1.

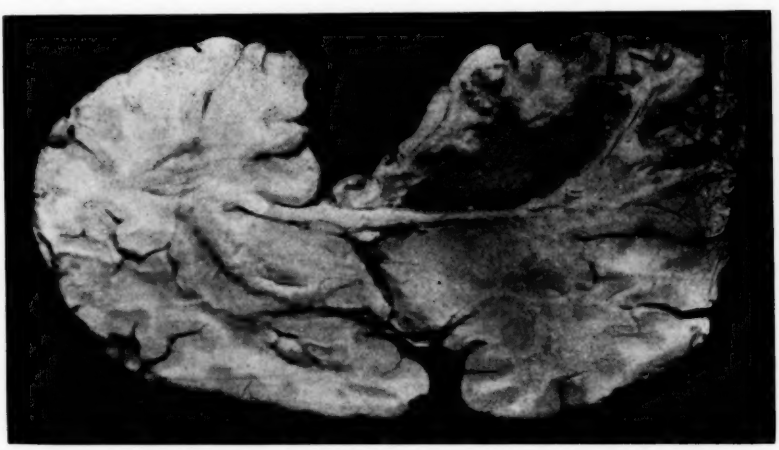

FIG. 2.—Photograph of cross section of brain, Case 1.

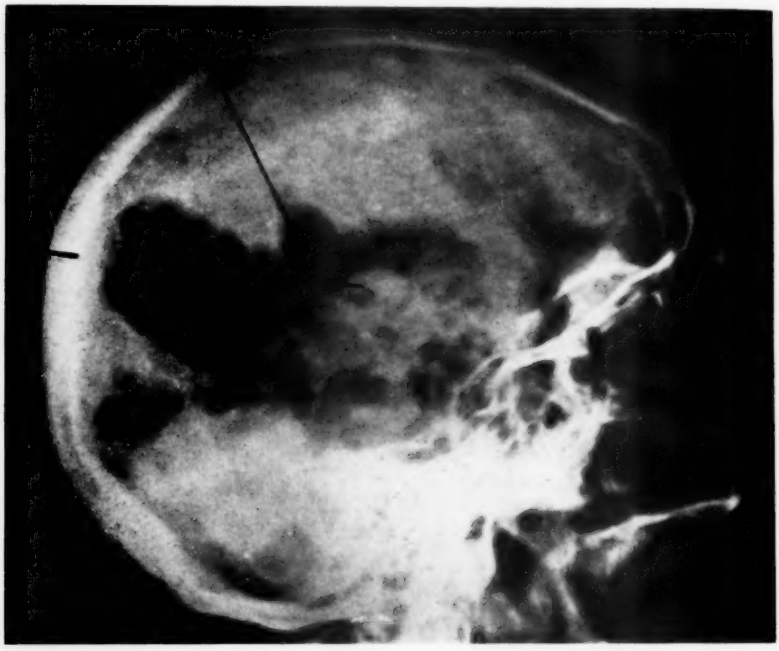

FIG. 3.—Encephalogram, Case 2, showing two areas of destruction. The lines drawn in show approximately the positions of the Rolandic and Sylvian sulci.

FIG. 4.—Encephalogram, Case 2, antero-posterior view.

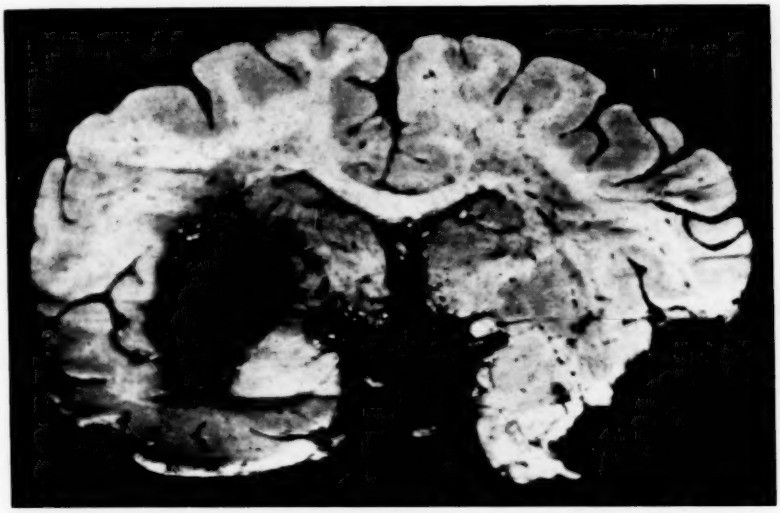

FIG. 5.—Photograph of the hemorrhage, Case 3.

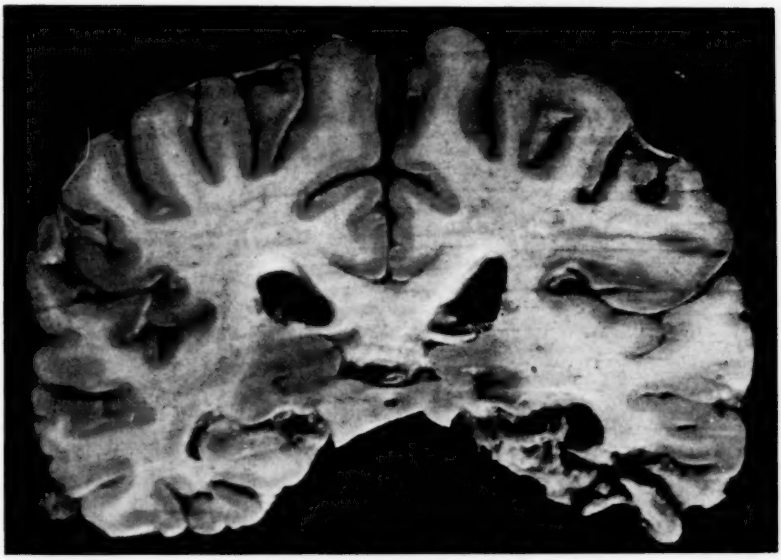

FIG. 6.—Case 4. Note softenings of (1) basal surface of left temporal lobe, (2) thalamus and (3) (slightly) of parietal lobe.

FIG. 7.—Reconstruction on a horizontal section of the softening and hemorrhage, Case 6. The parallel lines represent clot.

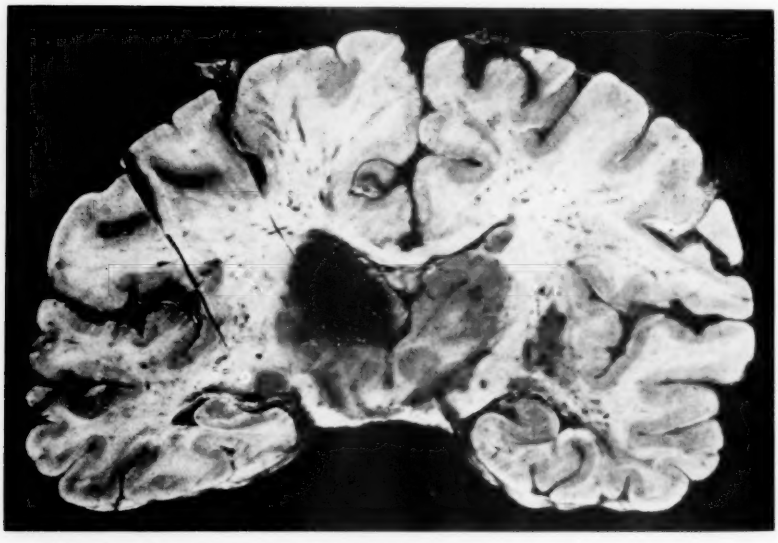

FIG. 8.—The hemorrhage in the thalamus, Case 7, at its largest part.

or indirectly (through edema and pressure) cut off, the conclusion would be that normally a considerable amount of mental activity takes place in the corpus striatum, thalamus and adjacent structures.

Incidentally the writer believes that the alert expression with or without the automatic eye movements is characteristic of preservation of the basal structures and is therefore of clinical, localizing value.

CASE 2.—*Encephalograms show large parieto-occipital and lower central lesions. The patient had almost complete motor aphasia, marked apraxia and a tendency to momentary confusion; yet he conducted extensive business affairs and in many ways displayed great mental acuity.* (Figs. 3 and 4.)

This amazing patient, a business man aged 60, had been stricken with apoplexy 20 months before the x-ray picture was made. His speech was confined to one expression of two words, which was frequently repeated, and to swearing when he was angry. The paralysis had improved only slightly and was still almost complete. He was markedly apraxic, even gestures often being incoordinate (though less so when involuntary or impulsive) and so easily confused that when under examination, his responses quickly became irrelevant and unaccountable.

At first the patient put out his tongue and touched his nose on request, but a moment later was unable to do so. Then he performed correctly the motion of turning a key and when a newspaper was handed him, he turned it right side up and glanced towards the headlines. But when shown a knife, watch, etc., he acquiesed whether the right or a wrong name was spoken. Told to write his name, he merely made a few scratches, but when told to write the name for a watch shown him, ended by trying to write his own name, although not succeeding. Asked to write the name of a finger ring shown him, he did nothing at all, and he could not indicate or write the value of various coins held before him. Then when shown a watch face and asked to write the time, he first wrote his name fairly legibly (perseveration), but slowly and with difficulty and finally an incorrect time in figures.

The history, however, told a very different story. This patient conducted his business affairs and managed several farms, through an agent who consulted him, and somehow made his desires known by the incoordinate gestures. Some months since he drew a plot of some farms which was without an error. He plans days ahead to visit a particular friend and when he happens to be in the neighborhood, does so. On one occasion the mysterious disappearance of cigarettes was the subject of discussion in the family circle and the patient eventually detected the culprit, an employee. Again when all were trying to recall the name of a certain person, the patient by his reactions disclosed that he was trying to let them know it. Eventually, in his excitement, the correct name came forth. Once when his nurse was startled and jumped at an unexpected sound, he laughed long and heartily. It was stated

that his mood is generally happy, although he can become very angry, and that he feeds himself unaided and propels himself everywhere in a wheel chair.

This patient's mentality undoubtedly is excellent and this in the presence of almost complete motor aphasia, marked apraxia and tendency to momentary confusion, and of lesions that cut off the visuo-psychic and other parts of the parietal and central cortex and destroy a large amount of the underlying white matter. The complicating factors mentioned and the difference between the accuracy of willed and impulsive responses account for the erroneous impression at first given by the examination.

The areas of destruction, as shown, are large, but no doubt are larger than those disclosed in the x-ray, which is merely the space from which, for some reason, the debris had escaped. The case, therefore, substantiates the conclusions drawn from the preceding one as to the comparative participation of cortical and basal structures in mental functioning. It also illustrates excellently the retention of mental capacity in the presence of almost complete motor aphasia. Altogether the case is an extraordinary and highly instructive one. (Permission to present this case has been accorded by Dr. W. T. Coughlin of St. Louis.)

CASE 3.—*Hemorrhage measuring about 2.5 x 2.5 x 5 cm., lying anteriorly and involving a small part of the caudate nucleus and a good deal of both the lenticular nucleus and island of Reil. Almost complete hemiplegia and marked hemianesthesia, but no aphasia and normal mentality.* (Fig. 5.)

The patient, a 48-year-old colored man, survived 21 days after being picked up in the street. The blood pressure was 220/140 and the physical condition was poor, the patient being emaciated and weak. The only movement that developed in the paralyzed side was a slight one in the leg. Sensation could be easily tested and marked hemianesthesia was demonstrated. No aphasia or apraxia was present. The condition remained almost stationary up to the second day before demise when the patient suddenly became weak and lost consciousness.

During the first day the patient was said by the interne to be stuporous and unable or disinclined to talk, but thereafter he was alert and mentally normal throughout. He conducted conversations on a number of subjects at different times and always responded quickly and accurately. His memory was excellent and he could follow a train of thought and draw conclusions as well as anyone of his station and race. He was quiet and unemotional. All commands were executed promptly and accurately. One could find no defect at all in the course of the type of examination which was used with such cases. He asserted that he was completely right-handed.

This case is interesting as showing where at the base a lesion can be located to cause hemiplegia without accompanying aphasia or mental involvement. Evidently some of the findings, such as the hemianesthesia, were effects at a distance. How speech escaped is rather a mystery. The case may be a type for those patients with right hemiplegia and normal mentality.

CASE 4.—*Large lesion involving the basal surface of the temporal lobe, smaller lesions affecting superior parietal gyrus and optic thalamus, very small lesion in second frontal gyrus. Typical jargon aphasia; mentality very good, but easily confused.* (Fig. 6.)

The patient was a 68-year-old, professional, white man. Onset of illness 20 weeks and beginning of observation 15 weeks before death. The physical and mental conditions varied little. For several weeks there was a typical jargon aphasia and thereafter the only vocal responses were an occasional "yes" and "no"; but gestures remained normal throughout. There was some apraxia for simple voluntary acts. The paralysis was partial in the beginning, but gradually became complete (flaccid) in the arm and almost complete in the leg. Sensation was easily judged by the facial expression and was markedly affected. The patient was said to have himself discovered his hemianopsia and tried to tell about it, before the doctor found it. His mood was at times lachrymose and he was at times rather drowsy. Unless accosted he was quite apathetic, although his appearance was one of alertness.

The patient obviously recognized all visitors and the family were sure they could tell when he particularly liked or disliked a caller. He invariably greeted his physician with a nod of recognition, a wave and the extension of his hand. He apparently recalled visiting the physician before the onset of his illness and being visited by him a few days previously. Some sample reactions are as follows: Asked who the doctor was there was a deprecative smile that stated, "what a foolish question"; and questioned as to how he was, the response was a grimace of futility that expressed, "what can one say in my condition?" Once when his beard was being discussed and he was asked if people had not occasionally taken him for a rabbi (a family joke), he replied with a prompt and vigorous nodding. He recognized the portrait of his daughter among several shown him. In addition he answered questions as to pain and for a time indicated when he required the bed pan.

But any succession of questions quickly confused the patient and "or" sentences were never grasped. The short simple remark or question seemed nearly always to be understood.

Post mortem there were the following areas of softening: (1) a large area involving all the basal surface of the temporal lobe up to 2.5 cm from the tip and extending as deep as the ventricle; (2) a band-like zone in the superior parietal gyrus adjacent to the angular-supramarginal gyri and involving a part of the latter; (3) a very narrow linear band of small extent just under the cortex of the second frontal gyrus posteriorly; and (4) an area 1 x 1 x 2.5 cm. in the lateral nucleus of the thalamus. The basal vessels were solidly calcified.

The mentality in this case was apparently very good if one accepts the impulsive response as a criterion and does not demand a consecutive train of thought. Retention of remote and recent memory and a grasp of many, albeit simple, questions and remarks would seem to imply as much. Certainly there was little of what is called clouding or confusion in the mental state. Evidently then there can be very good mentality in the background of jargon aphasia even though the patient does not seem to be aware of his speech disturbance. A final feature of interest is the exclusion of a part of the lateral nucleus of the thalamus from a rôle in the production of intellectual defect in the sense adopted for these studies.

CASE 5.—*Poor preservation, but apparently bilateral moth-eaten condition and scattered small areas of softening in the base. Cortex grossly normal. Little aphasia. Marked dementia.*

Sudden onset of right hemiplegia in a negro man of 74 years. The condition changed little during the 43 days between onset and death. The patient was able to speak some few words understandably in a hoarse whisper and attempted to speak others that could not be made out. He gave his name and repeated words after the examiner. He attempted to execute simple commands such as touching his nose and putting out his tongue, but rarely was completely successful. He laughed slightly when stuck with a pin and obviously felt the pricks more strongly on the left side. He seemed to recognize his name among several pronounced. There was no response unless the demand was simple and spoken in a loud voice. Little stupor or drowsiness was evident. He had to be fed at all times and evacuations were involuntary.

The autopsy had been performed four days post mortem and the brain markings were indistinct due, no doubt, to poor preservation. The great nuclei, particularly the thalami, were apparently moth-eaten and atrophic and a number of areas of partial softening of less than a centimeter in diameter appeared to be present. There was no definite softening of any size. The cortex was better preserved and was approximately normal. The larger arteries were solidly calcified.

(In a similar case, the patient was 65 and the mental changes at first less marked, but gradually becoming more pronounced. Total duration of illness nine days. The pathologist was able to find no gross lesion at all, only an "edema.")

Unsatisfactory as this case (and the other) is, it suggests several instructive points. In the first place sudden onset, particularly in the aged, evidently does not establish the existence of a single, limited lesion. Again hemiplegia and perhaps mental defect may be caused by extremely small lesions. Finally it may be found that the most profound and permanent of defects are associated not

with single, but with widespread and bilateral processes in the basal structures. The case is, therefore, useful in putting us on our guard.

CASE 6.—*Band-like hemorrhage and softening, approximately 1.5 across, 2.5 cm. high and 6 cm. long in the greatest diameters, running antero-posteriorly and involving all of the central nuclei. Partial hemiplegia. Moderate to marked mental confusion. First positive case* (Fig. 7.)

The patient was a negro woman, aged 29, with the blood pressure 225/150, negative blood, spinal fluid and urine tests, and the history of a sudden stroke three days before entry. Speech was said to have been affected at first, but upon entry she could give some of her personal history, although not entirely clear mentally. She quickly became drowsy and more confused. The evacuations were involuntary throughout and she had to be fed almost from the beginning. The spinal fluid on the second and seventh days was clear. On the eighth day the blood pressure fell to 100 and the patient became stuporous, dying on the ninth hospital day.

Examined on the fourth day the paralysis was found to be definite, but not marked. Sensation could not be tested owing to the mental state. General condition excellent. The patient was drowsy, but could be aroused. Her capacity to speak was retained at least to a large extent, but she was quite unresponsive and disinclined to talk, such answers as were obtained being generally in monosyllables. She could give her name and even was able to state that she had suffered a stroke a few days before. She recalled having seen previously two or three of the doctors and nurses present, but it was not certain that she recognized their function or the nature of the institution. She would execute slowly, but sometimes only after repeated commands such simple actions as touching the nose and putting out the tongue. The patient's disinclination to respond and cooperate in any way interfered decidedly with the examination. The conclusion at the time was that she was "considerably confused." The nurses and doctors in attendance agreed that she had been markedly drowsy and mentally affected certainly after the first day or so. On two or three occasions she had failed to recognize visiting relatives. Altogether the evidence definitely indicates that the mental confusion was from moderate to marked in degree.

Post mortem, besides the lesion itself a liquid mixture of blood and spinal fluid was found in the ventricle and a small, soft, unattached clot in the posterior horn. The cerebral arteries were not calcified or thickened.

The lesion in this case is of limited extent and destructiveness and we may safely conclude that the mental confusion was due largely to the actual destruction with perhaps some slight reaction on immediately adjacent tissues. The post-mortem findings of blood in the ventricle and of the small clot in the posterior horn probably originated coincidentally with the fall in blood pressure the day before death, since the spinal fluid two days before death

was clear. The case, therefore, is important as showing one locality in which a limited lesion can lead to definite mental confusion.

CASE 7.—*Cone-shaped hemorrhage with the base posterior lying entirely within the thalamus; greatest diameters 30 x 25 x 13 mm. Hemiparesis; no aphasia. Confusion increasing from moderate to marked. Second positive case.* (Fig. 8.)

The patient, a colored woman, was probably 46 years old. While being driven home by her white employer, she began to vomit and became speechless. The blood pressure at different times on the day of entry was 180/130 and 140/94. The blood and spinal fluid Wassermann tests were twice negative, but the spinal fluid Kahn was respectively three plus and four plus. A history of anti-luetic treatment was later obtained.

The right side of the body was at all times definitely weakened. Sensation could not be tested owing to the mental condition. Speech was invariably possible and probably unaffected, but the consistent disinclination to respond made all testing difficult.

Three days after entry the patient was not in shock, but appeared ill in disproportion to the paralysis and she was dull and apathetic. She gave her name and realized that she was in a hospital and in answer to questions stated that she had suffered a stroke while on the way home from work. Answers were monosyllabic and generally were obtained only by leading questions. Simple commands were correctly executed. The nurse stated that she was "off" at times, had to be fed and was "involuntary" at all times. The impression was that she was definitely confused, although it was thought that local shock in the brain might still be present.

Three days later the patient was still more unresponsive. She still realized she was in hospital, but first gave an incorrect name and then could think of no other. She did not appear to recognize the doctors and nurses who had been attending her and said she had not had breakfast or lunch although the time was afternoon. She could answer questions as to her name, pain, hunger and the like and execute simple commands, but failed to answer many questions and some replies were unintelligible mumbles. She was thought to be "considerably confused." Thereafter on several examinations the condition was found to be almost the same, except that the mental confusion steadily became somewhat more marked, until two days before the end when she became generally spastic, tremulous and stuporose. Death 30 days after onset.

Examination of the brain showed a roughly conical clot, lying entirely within the thalamus, that filled the pulvinar and extended diagonally forward in decreasing size to terminate near the anterior extremity of the organ. An area of blood-stained softening 1 cm. x 3 mm., continued a short distance into the capsule. About midway the diagonal portion, 2 cm. x 6 mm., was wedge-shaped and ran through the center of the thalamus from a point at the lower extremity of the ventricle to a base at the upper lateral limit. The size in the pulvinar was 25 x 13 mm. Otherwise the brain was entirely normal and the basal vessels were only slightly sclerosed. Upon microscopic examination no perivascular infiltration of cells was found.

This excellent case is valuable because the attending symptoms were probably mostly due to the actual destruction along with, of course, some slight pressure on nearby structures. The increasing severity of the clinical findings may have been due to a continued oozing of blood, although this point could not be established from the clot itself. The lues was probably not a contributing factor in the mental symptomatology.

If this case is contrasted with Case 3, the importance of the factor of location becomes glaringly apparent.

These cases in which clinical and anatomical findings are correlated provide several important links for the chain of negative and positive evidence. The first two cases taken together strongly indicate, if they do not definitely prove, that the cortex of the area being investigated plays no special rôle in the production of the type of intellectual defect described. Several of Dandy's cases, notably two in which Broca's area was removed,[8] and the one, mentioned above, in which the incision was located forward almost to the post central gyrus, in all of which a great deal of this part of the cortex was excised go far towards supporting the same thesis.

Case 3 continues the process of elimination and clears the anterior portion of the basal structures, namely the caudate (in part) and lenticular nuclei and structures immediately underlying the island of Reil of participation; while Case 4 goes still further by excluding a part of the lateral nucleus of the thalamus and some of the basal cortex of the temporal lobe probably not included in the various surgical ablations.

Thus the process of elimination has so far extended to all structures excepting parts of the optic thalamus and adjacent structures. The two positive cases complete the pictures by exhibiting lesions of these very structures. These two cases are almost ideal in that other factors than the actual destruction appear to be reduced to a minimum, although certainly not absent altogether.

As was pointed out in the case reports, these cases also bring out several other important points. Case 1 serves to correct the erroneous impression given by Dandy's cases of ligation of the anterior cerebral artery that the resulting lesion necessarily causes complete and permanent loss of consciousness. Case 2 both shows some

of the complications to be allowed for in evaluating intelligence clinically and illustrates the retention of good intelligence in the presence of motor aphasia. Case 4 indicates that very good intelligence can be maintained in the presence of jargon aphasia. Case 5 sounds a warning note for clinical and to some extent for pathological studies.

By the negative and positive evidence, therefore, a quite small area lying posteriorly near the base of the brain is definitely implicated as being that responsible, when injured, for "clouding," "confusion" and "dementia." This conclusion is in substantial agreement with that of Marie published 30 years ago. The conclusion, however, is still to a degree tentative because there are too many uncertain factors for a few cases, however suitable, to be decisive.

Summary and Discussion.

To sum up the evidence briefly, (1) the various surgical excisions of Dandy and others and the observations of left vascular hemiplegia serve to exclude from a part in the production of essential intellectual defect all areas of the brain except that under investigation; (2) clinical studies of many cases of right vascular hemiplegia, wherein the lesions are generally in the area being studied, are useful in defining and delimiting the intellectual defect and indicate that this is, at least for the most part, a separate and distinct symptom or group of related symptoms; (3) correlated clnical and pathological studies, among a number of instructive points demonstrated, apparently exclude the cortex of most, if not all, of the area under consideration as a source of intellectual defect and likewise the anterior portion of the base, while two cases directly implicate the posterior portion of the basal structures.

No elucidation of the several findings considered singly and together other than the one of the location of the lesion, has suggested itself during the course of the studies. Such factors as the size of the lesion, the acuteness of its onset, effects at a distance from circulatory or mechanical effects or an unsuspected peculiarity of handedness or combinations of these factors are found not to be sufficient, in view of all the findings and the number of cases observed, to account for the various results. Still it is possible that the most profound and permanent defects are found only in con-

nection with widespread involvement; thus if the functions should grade away from a peak, many lesions might produce no appreciable effect, others partial defects and only extensive lesions the most severe and lasting involvement. Although more cases are required to give assurance in a field so novel as this one still is, the main conclusion appears to be amply justified.

The criterion adopted, that of the preservation of the essential intellectual functions (without regard to the details of memory, learning capacity, scholarship, emotional stability, initiative, etc.) or of the defects of these functions as the psychiatrist knows them has proved to be reliable and satisfactory. For more reasons than one, it is not justifiable to apply to these patients the standards set up for normal people. For one thing physical and circulatory changes within the skull after a severe episode will generally affect the highest performance even though the mental functions are themselves not actually involved. Assuredly qualitative changes are a better index to actual involvement than are quantitative alterations; otherwise most of us could be convicted of having a defect every few days.

No attempt has been made to determine what may be the nature of the functions, injury to which gives rise to the intellectual defects being studied. Obviously the nature of these functions means a great deal towards the understanding of the physiology of mental activity and will have to be investigated in its turn.

The *implications* of the conclusion reached are both broad and important.

One of these is the too great reliance which scientists have placed on the cortex in connection with mental processes and related functions. Dandy and, no doubt, others began to recognize the extent of this error when large excisions of brain tissue did not result in a comparable disturbance of these functions. Now the basal structures, particularly those of the left side, take on added significance and many readjustments in accepted conceptions become necessary. That the remainder of the brain may complement, complete and intensify does not alter the fundamental conclusion.

Another point is that we may have been searching all these years in the wrong spots for the anatomical changes of mental disease, epilepsy and similar disorders; logically the first place to look for such changes is where mental functions are chiefly subserved.

Still another implication, as Dandy mentions, is that the frontal lobe syndrome, so-called, may not be of frontal origin at all, since surgical removal of these lobes has been unaccompanied by the findings to be expected. The "crowbar man" may have suffered from irresponsibility and patients with frontal tumors may exhibit levity, prankishness and excitability not through any actual destruction, but from indirect pressure and circulatory disturbance acting on nearby structures. As the thalamus has been credited with possessing powers over emotional control, this may be the organ concerned; in which case the change of character would be due not to a loss of higher moral or intellectual conceptions, but to the eruption of emotional factors released by a disturbance at their seat.

Conclusions.

Reports of surgical operations in which various parts of both hemispheres were removed and of cases of left hemiplegia lead to the conclusion that intellectual defect *per se* is not produced by lesions other than those of the central portion of the left hemisphere in right-handed persons. A clinical study of cases of right hemiplegia affords a clearer conception of the nature of the intellectual defect produced by focal lesions and indicates that this is an affection or group of related affections more or less separable from defects frequently associated with it, such as aphasia, apraxia, paralysis, sensory loss and emotional disorder. Correlated clinical and pathological studies of seven cases, among a number of corroborative points brought out, serve to localize still more exactly the structures from which intellectual defect is produced by injury, both negative and positive evidence indicating that these occupy a relatively small area situated posteriorly in the basal region of the brain. The implications of this conclusion seem to be extraordinarily far-reaching.

DISCUSSION.

DR. CHARLES ENGLANDER (Newark, N. J.).—Dr. Alford's paper is interesting from the standpoint of the types of patients and the lesions which he demonstrated, but it scarcely seems fair on the inferential basis to make such wide assumptions as the Doctor does. I was taught to believe that the basal ganglia are subordinate to the cortex. I don't think the Doctor has introduced any evidence here this morning to change that view.

The clinical features which his changes show are not unique. They are the sort that most of us have been seeing in lesions of this sort, and if we were to assume that intelligence was restricted to such a narrow area within the cerebrum, I am afraid that our psychiatric implications and our neurological implications would become tremendously more chaotic than we now see in such features as studies in aphasia and in our studies on intelligence.

I have the feeling that if the Doctor's patients had survived long enough to have been studied from the standpoint of intellectual defects and from their ability to learn new things, perhaps his conclusions would be altered.

I am not satisfied that the lobectomies which the neurosurgeons are doing and the excellent reports which have been coming to us in partial ablations of the frontal lobes are altogether satisfying. It is my impression that what we are learning from these facts are: That the brain can get along without some parts of the frontal lobes or some parts of both frontal lobes, or total lobectomies, and that all we have learned is that the brain still has these tremendous potential abilities for adaptation after large portions of the cortex and white matter have been removed.

To assume that so much of intellectual activity is in the basal ganglia is rather farfetched.

DR. RAYMOND C. FAGLEY (The Bronx, New York).—Dr. Alford in attempting to localize the area of intelligence in the brain states, "The general conclusion is, therefore, that general intellectual defects develop only after injuries of a limited area of the left base."

From the experience of Dandy, and others, it would seem that intelligence is not to be located in the frontal lobe of the brain as has been formerly thought. But many still believe that in the frontal lobe, the final correlation of sensory impressions takes place, and its development is coordinate with the growth of intelligence and culture.

Dr. Alford's study of the brain was "restricted to the middle portion of the left hemisphere, the vascular accident with right hemiplegia; particularly thrombosis and embolism afforded a useful source of material—accordingly material of this nature has constituted the chief source of data." Focal lesions in this area usually result in hemiplegia on the right side, associated in some cases with aphasia.

I do not believe that the localization can be satisfactory in cases of thrombosis and embolism, especially thrombosis, because there can be and usually are other arterial changes present in the brain. It is true that sometimes one has great difficulty in determining the amount of intelligence in the presence of a well-marked aphasia.

The question of defect in intelligence in the various types of aphasias has been a subject of controversy. This must be considered to apply only to local lesions and not to softenings occurring in senile or arteriosclerotic brains. Intelligence, in its broadest sense, is affected, but Head rightfully insists that thought may be going on without symbolization or internal speech. But, obviously, the patient cannot "think to himself." His acts may be correct, but they seem automatic. His difficulty in a world of beings using symbols in every procedure leave him utterly alone, without a chance of social intercourse. His intelligence is one which is portrayed only in his spontaneous actions.

Weisenburg, after a life-long study of aphasia, finally concluded that it is not possible to localize definitely aphasic disturbances. Psychologic studies have shown that speech disorders go far beyond the lingual process. Speech depends upon the unified activity of the whole brain associations.

Grinker states, "It is obvious that such faculties as consciousness, intelligence, memory, speech and life phenomena cannot be localized to any one part of the brain."

Aphasia and defects of intelligence are very closely allied, and if ever we localize the aphasia center we will be close in localizing intelligence, or perhaps the process may be reversed. It has been demonstrated in right-handed people that coherent speech can be reëstablished in lesions of the speech center of the left side of the brain. It is thought that a speech center is established in the right side in these cases. It is possible that in some people, there has been established during growth a speech center in both sides of the brain. This could account for the failure of aphasia to develop in lesions of the left side of the brain, where we ordinarily would expect to find that condition.

Dr. Alford, in his series, studied 50 cases with left-sided hemiplegia, all of whom gave negative results for intellectual involvement. He states, "Excisions of the right hemisphere does not take into account the central nuclei,

the lenticular and caudate nucleus and the thalamus." The 50 cases taken at random from material at an infirmary all gave negative results for intellectual involvement, while 50 control cases of right hemiplegia gave a different result. From this observation, he has eliminated lesions of the entire right half of the brain from cortex to base as the source of mental defect.

I recently examined an Italian, age 48, who came to this country at the age of 14 years. He is right-handed. He shows a hemiplegia on the left side, including a lower facial paralysis, a speech disturbance, and a defect in intelligence. There is no history of lues and serological examination is negative for syphilis. The blood pressure is 214/154.

He had his first stroke while at work in September, 1931, with a slow onset and without losing consciousness. For three or four weeks he had a speech difficulty, and was hard to understand. About one year later, he began to show an irritability, neglected customers, and became somewhat forgetful. If he did not write down a telephone order immediately, he would forget it. He carried on his business until December, 1936, when he had another stroke while asleep. Following this he was unable to talk until March of this year. Since March, he has been having emotional outbursts of weeping. He knew everything that was said to him, but he could not speak. At the present time, he articulates fairly well, but every once in a while the words run together and one cannot understand him. In writing his first name, Joseph, he left off the "h" but as soon as this was called to his attention, he recognized his error. The address with the street number was spelled correctly. He was then asked to write his name in Italian. Again he made a mistake in spelling his first name, Guiseppe, leaving off the last two letters. When called to his attention, he again corrected the spelling.

Although his attention was good and he was not confused, retention and immediate recall memory was faulty. He was given the number 654321, and the address of 130 West Kingsbridge Road, and after being repeated to him several times, he was told that in five minutes he would be asked to repeat. Two minutes later he was unable to recall any numbers but 64, and gave the address as 130 Kingsbridge West. Although 12 days in the hospital, he could not name the nurse or attendants. You certainly cannot say that this man was normal mentally.

Superficially, there may not appear to be any memory or intellectual defect, but on closer examination of the patient, a well-defined defect in the intelligence is obtained. This man had been in business for 25 years, and had made a success up to the time of his first stroke. Although he continued for five years, he lost business and finally closed his store in December, 1936.

The causative factor in this case is undoubtedly a thrombus on the right side of the brain, but with a blood pressure of 214, I do not think we are justified in limiting the lesion to one particular area, only.

In brain tumors, we have pressure symptoms to deal with in addition to the focal signs. Dr. Alford, quoting Dandy, states, "The entire body of the corpus callosum may be split in the midline without any appreciable

disturbance of function. This structure is, therefore, eliminated from participation in the important functions which have hitherto been ascribed to it."

There are many cases reported in the literature which show that involvement of the corpus callosum did show abnormal findings. Trescher and Ford report a case of colloid cyst of the third ventricle which was removed by the posterior approach and the posterior half or more of the corpus callosum was sectioned during the operation. Reasons were given to support their belief that section of the corpus callosum was the only significant injury inflicted on the brain. After the operation, she was completely disoriented for time, place and person, for a period of three weeks. She had an inability to form and retain topographic memories so that she would become lost in her own home. Although there was some improvement in this later condition, yet four years after this operation she still showed loss of sense of direction.

Voris and Adson reported mental findings in 92 per cent of a group of cases with tumors of the corpus callosum. This percentage is even higher than is usually found in frontal brain tumors.

In conclusion, I do not fully understand the extent of the intellectual field that Dr. Alford is trying to cover. Is it the emotional field, the sensorium, mental grasp and capacity upon which findings we ordinarily establish an estimate of the intellectual capacities and resources of the individual? The preponderance of evidence today shows that there is no specific localized area of either aphasia or mental defect, but Dr. Alford has given us an idea that I think warrants further study, especially the importance he has brought out concerning the negative findings.

Dr. William Nelson (St. Louis).—We owe a great deal to Dr. Alford for raising this question, particularly since in more recent years we have become interested in trying to define what constitutes intelligence. In the first place, we cannot think of the functions of the human organism without considering the individual as a total personality representation. We cannot isolate certain aspects of reactions or perceptions and reactions on the part of human beings and consider that we are covering a certain field that would represent intelligence, and, therefore, in any consideration of what constitutes intelligence, we must think of the total representation of that individual.

We are taking most of these cases, for illustration, from rather the decadent period of life, if you will, at least the period of life in which all of us begin to deteriorate somewhat, and there are other correlated conditions that exist in many of them which we cannot extricate from the possible influence upon such a condition. In addition to that, we have an historic past of individuals that we cannot discount and consider the situation only from what we find at the time. Take any one of us and have us deprived of our avenues of perception, or our mechanisms of response, suddenly as a result of some lesion, and you will find all sorts of confusions on the part of the individual—I don't say every individual, but with a great many of them you will find as many confusional reactions on the part of that individual as a result of

being deprived of a mechanism of response that has been familiar to him and has been cultured and developed over a period of years.

Those are things that come into consideration in estimating the intelligence of these people. When we come to a consideration of this, then I dare say we are not justified in concluding that over a relatively temporary period following the incidence of these lesions that an individual reaction, confused or deprived state, that we are justified in concluding that that is the intelligence.

I want to comment somewhat on Dr. Englander's remarks: I think he is right to conclude that we do not have a narrowed area of representation that embraces the broad function of intelligence. Intelligence is a very complicated and complex matter, and no doubt the basal ganglia, the peripheral nerves, the spinal cord—all of the tissues and organs of the body participate in what we recognize today as intelligence.

Most of us are familiar with the work that Shepherd Alvery Franz did several years ago up to the time of his ultimely death, in reëducating individuals that had lesions such as Dr. Alford has described or illustrated for us, and he found that there was a restoration of function commensurate with the reactions of the individuals that he had under study and under reëducation, so that the question of intelligence is a broad one that we cannot draw analysis from or react inferentially toward and I do not think that we have our intelligence represented in such a narrow phase of cerebral organ or cerebral tissue that deletion of a certain aspect of it is going to represent the loss of function on the part of that individual.

Let us think of the ambidextrous people, or the people who have to change from righthandedness to lefthandedness. What happens? We have some people who have been righthanded all their life, whether normally or not, and through some reason or other they change to lefthandedness, or we have the individual who is ambidextrous; how is their intelligence going to be represented?

Those are some questions that I would like to bring up for consideration.

Dr. Leland B. Alford (St. Louis, Mo.).—I realize how revolutionary these views are, and I probably shouldn't have had the nerve to bring them up if the surgeons hadn't been expressing similar views for a number of years. So there has been a tendency in this direction for some time. I didn't bring out part of the paper. I have observed clinical cases over seven or eight years, and, therefore, these few anatomical cases are backed up by a great many clinical cases. There hasn't been anything inconsistent, however, in the clinical cases. Occasionally one does find a left hemipleiga with involved mentality, and I have had autopsies on those cases. In one autopsy the lesions were bilateral, and in Dr. Fagley's case, the fact that speech was affected would indicate that it was a lefthanded man.

As to the time element, I know that should come in; it should come in in proportion to the severity of the lesions; the last case was 30 days, with a small hemorrhage. That should eliminate the shock element.

As to the findings of some of the men in section of the corpus callosum, I want to aagin emphasize the force of the negative finding over the positive finding. There are so many secondary factors that come in. There are pages that tell about the mental changes in connection with lesions of the right hemisphere. However, I think one negative case or two negative cases would overrule all of those, merely because of the possibility of secondary factors, circulatory changes, pressure, and that sort of thing. I chose what most psychiatrists call intellectual involvement, that is, clouding or confusion. It is a pretty definite term. It doesn't include emotional disturbance.

I don't think it is right to include total performance. A man with a big hole in his head near such vital centers shouldn't be expected to carry on mentally as a normal person would do.

As to the ambidextrous, I have a patient now who is ambidextrous, with a right hemiplegia, very mild, and he shows mental confusion, just the same as the patients who claim they are righthanded. Whether that would hold out in all cases, I don't know.

In conclusion, I think the evidence is all too consistent, the negative evidence in certain cases and the positive evidence in others, to be ignored.

SODIUM AMYTAL AS A SUBSTITUTE FOR TUBE FEEDING.*

By WILIAM H. FOLEY, M. D., AND VINCENT P. ROSSIGNOLI, M. D.,
Resident Physicians, Psychopathic Department, Charles V. Chapin Hospital, Providence, R. I.

In every psychiatric institution, there are always patients who are problems in that they persistently refuse nourishment, either liquid or solid. These cases present the dilemma that, on the one hand, rejection of food tends to prevent or delay recovery, and, on the other, tube feeding has disadvantages and dangers. Feeding is relatively simple in cooperative patients, but in active, resistive patients it gives rise to many complications. The patient may hinder the passage of the tube to such an extent that trauma with subsequent infection of the nasal, pharyngeal passages may develop. Even though the tube is properly passed and the feeding in progress, the patient may vomit the tube or the gastric contents and aspirate some of the tube feeding, thereby developing an aspiration pneumonia or a lung abscess. Moreover, to supply adequate nourishment in calories, vitamins, minerals and bulk by tube feeding is difficult and inexpedient. Patients tube fed over a long period usually lack some essential requirements of a well-balanced diet and suffer from this deficiency as a consequence. Often a severe diarrhea results which can be controlled only by the discontinuance of the tube feeding.

In certain cases admitted to the psychiatric wards of the Charles V. Chapin Hospital, we had this problem to contend with. It was recently observed that sodium amytal given either intravenously or intramuscularly eliminated the necessity of tube feeding as patients invariably took nourishment after the administration of this drug.

We had the opportunity to experiment successfully with ten patients: five were cases of schizophrenia, and two of post-partum psychosis with a schizophrenic background; one had pulmonary

* Read at the meeting of the Rhode Island Society of Neurology and Psychiatry, April 12, 1937.

tuberculosis with a toxic psychosis following a first stage thoracoplasty; one was diagnosed psychosis with cerebral arteriosclerosis; and another, an extremely active and resistive patient, was treated for general paresis.

In two cases the drug did not react as we had expected, but a fair trial was not given as one patient began eating and the other was discharged against advice. The first was an active, negativistic patient who was under treatment for involutional melancholia complicated by diabetes. She became more excited after small doses of the drug and in larger doses went to sleep. The second patient, a cerebral arteriosclerotic and hypertension complicated by auricular fibrillation, was also active and negativistic and became excited with the drug. These two cases were not studied sufficiently to ascertain the correct dosage of sodium amytal as a substitute for gavage, before one suddenly became better and the other went home against advice.

In the group of cases with whom the drug was effective, the ideal reaction was observed in the depressed catatonic reaction rather than in the active manic state, regardless of the type of psychosis with which we were dealing. However, in the case of the paretic who refused all nourishment and medication by mouth, the sodium amytal was most helpful as all other parenteral sedatives were without effect, unless given in very large doses and then over a period sufficient for cumulative toxic effects. Under small doses of sodium amytal he was fed and given paraldehyde which was continued thereafter without sodium amytal. Paraldehyde was the sedative of choice to carry him through his active psychomotor state to prevent death from exhaustion or injury. It was also interesting to notice certain patients in this group who had previously refused all food and had been absolutely mute, suddenly eat and talk. Most of them could not explain why they had refused food and suffered the discomfort of a tube feeding and then, under sodium amytal, asked for food.

We observed that the same effect could be obtained whether the drug was given intravenously or intramuscularly. When given intravenously, however, the patient took solids or liquids immediately after the needle was withdrawn from the vein and the desire to eat and also talk usually lasted from 10 to 15 minutes.

When injected intramuscularly, the patient began to take nourishment 15 to 30 minutes afterward and the effects lasted 15 to 30 minutes. Sometimes a patient took fluids one and a half hours after the intramuscular injection. It was noticed, too, that solid foods, unless especially well-liked, were not taken as well as fluids when the drug was given intramuscularly and even then had to be more or less forced.

The optimum dose for the required action has not been satisfactorily decided. This varies, however, with the type of patient, the weight, age, activity or depression—all are factors to be taken into consideration. Our doses varied from $3\frac{3}{4}$ grains to $7\frac{1}{2}$ grains when given either intravenously or intramuscularly. The desired dose causes a semiconscious state and is determined only after one or two trials. If the dose is too small, the desired reaction does not follow. On the other hand, if it is too large the patient will fall into a deep sleep. It is unwise to force fluids or solids on patients who have had an overdose of the drug for in such cases there is a certain amount of paresis of the muscles of deglutition and forcing nourishment too quickly before the patient can swallow may cause some of the food to enter the trachea and bronchi. To illustrate this—one of our cases, a man who was being X-rayed for a G. I. series, refused to drink the barium preparation. He was then given sodium amytal intravenously and willingly began to drink the solution. He was forced to drink the barium too quickly and, as a result, started to cough and became slightly cyanotic. He was fluoroscoped immediately and the barium was seen in the trachea and bronchi and also in the stomach. This would not have happened if the barium had not been forced more quickly than the patient could drink it. One patient in our series ate after only one intravenous injection, others after a few days. One patient was given sodium amytal for weeks, but she was later transferred to the State Mental Hospital and could not be followed. There was no evidence of toxic symptoms in these cases.

Whether or not these same ten cases might have progressed more favorably and eaten sooner following tube feeding is doubtful. However, under sodium amytal all ate, talked, gained weight, received a well-balanced diet and developed no diarrhea. They were less resistive and negativistic, and also indirectly obtained needed rest and sleep following the administration of the drug.

PRIMARY AFFECT HUNGER.*

By DAVID M. LEVY, M. D., New York, N. Y.

In a previous study of maternal overprotection, an investigation was made of a mother-child relationship featured by an excess of maternal love. This excess was demonstrated overtly in maternal behavior through physical and social contact with the child, infantilization, extra precautions and protective behavior. Definite criteria of a relationship were set up, and cases selected, out of a large number, in which the criteria were satisfied. Case studies were thereby utilized in the form of an experiment, as though to say: If we could make an experimental study of such a relationship, we would have to satisfy certain conditions. Let us see if in a large body of case material such conditions are already satisfied. Naturally, the more definite and numerous the criteria the fewer the number of cases that can be filtered out by this process. The advantage, however, is that the greater the selectivity, the "purer" the relationship to be studied.

During the study of maternal overprotection, it was necessary to select, for the purpose of contrast studies, cases of maternal rejection. In the latter group, however, selective criteria were never adequately worked out. Since the investigation of the overprotective groups was terminated by the closing of the Institute for Child Guidance, a staff was no longer available for study of the numerous details that were part of the undertaking. In the absence of such aids to a companion study of maternal rejection, it is necessary to have recourse to a simpler method. I must therefore, in this paper, utilize illustrative cases to indicate certain basic dynamic principles, without statistical aids. Furthermore, this study is limited in its orientation to the child who suffers the rejection. It is also limited to the experience of a certain type of rejection, to which I am applying the name "affect hunger."

The term, affect hunger, is used to mean an emotional hunger for maternal love and those other feelings of protection and care

* This and the following five papers, constituting a symposium on child psychiatry, were read at the ninety-third annual meeting of the American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

implied in the mother-child relationship. The term has been utilized to indicate a state of privation due primarily to a lack of maternal affection, with a resulting need, as of food in a state of starvation. Since the symptoms of affect hunger are clearly manifested in children who receive maternal care and direction to a high degree in a physical and intellectual sense, though without any evidence of affection, the analogy is more accurately related to a vitamin deficiency rather than to a gross starvation. The use of the term affect hunger, rather than affection or love hunger, opens the possibility, also, of a privation of other sources of the emotional life, even possibly of hostility, though this is yet to be investigated. A child who has been overprotected and later, through the birth of another child, thrown into a rejected state, may also suffer affect hunger. In the present paper, however, I am using the term to apply only to individuals who have suffered lack of maternal love in the early years of life. Assuming for the moment the value of maternal love as an essential component in the development of the emotional life, what happens when this element is left out of the primary social relationship? Is it possible that there results a deficiency disease of the emotional life, comparable to a deficiency of vital nutritional elements within the developing organism?

My first example is an eight-year-old girl who was adopted a year and a half before referral. After a illegitimate birth, the child was shifted about from one relative to another, finally brought to a child placing agency, and then placed in a foster home for two months before she came to the referring foster parents. The complaints were lying and stealing. The parents described the child's reaction to the adoption as very casual. When they brought her home and showed her the room she was to have all for herself, and took her on a tour of the house and grounds, she showed apparently no emotional response. Yet she appeared very vivacious and "affectionate on the surface." After a few weeks of experience with her, the mother complained to the husband that the child did not seem able to show any affection. The child, to use the mother's words, "would kiss you but it would mean nothing." The husband told his wife that she was expecting too much, that she should give the child a chance to get adapted to the situation. The mother was somewhat mollified by these remarks, but still insisted that something was wrong. The father said he saw nothing wrong with the child. In a few months, however, he made the same complaint. By this time, also, it was noted that the child was deceitful and evasive. All methods of correction were of no avail. A psychoanalyst was seen. He recommended that the parents stop all correction and give the child a great deal of affection. This method was tried, according to both parents, with no result. The school teacher complained of her general

inattention, and her lack of pride in the way her things looked. However, she did well in her school subjects, in keeping with her good intelligence. She also made friends with children, though none of these were close friendships. After a contact of a year and a half with the patient the father said, "You just can't get to her," and the mother remarked, "I have no more idea today what's going on in that child's mind than I knew the day she came. You can't get under her skin. She never tells what she's thinking or what she feels. She chatters but it's all surface."

I have selected this case as my first illustration of a type of difficulty that is familiar to everyone who works with children, because I feel reasonably sure that the parents were distinctly affectionate with children, and also because their own child, aged twelve, was affectionate and well adjusted.

Repeated experience in the treatment of the type of child referred, indicates a poor prognosis. Before considering this phase of the problem, I would like to cite further examples.

An unmarried woman, aged forty, adopted a child aged two years and eight months, through private arrangement. The child was the illegitimate son of a woman of high economic and social status. The family history was negative. The child was turned over to an agency very soon after birth, placed in an orphanage from age 12 to 27 months and then transferred to a boarding home, where he remained until the period of adoption. After a year, the mother gave up the possibility of getting any emotional relationship with the child. She had never been able to get any sign of affection from him. He never accepted her fondling. In the household there was a doting and indulgent grandmother, to whom the child also did not respond. The mother felt she had been taking punishment for a year and could stand it no longer. Besides the lack of emotional response, she complained chiefly of his negativistic behavior. According to tests the child had superior intelligence, and the physical examination was negative.

The third example is that of a boy adopted at the age of three. The previous history was unknown, except that he was illegitimate and had been shifted around from place to place. A Wassermann test and physical examination made at the time were negative. I examined him at the age of eight years. There was a good health history, and the physical examination was negative. According to tests, the intelligence was adequate. He was referred because he had been twice suspended from school for poor work, and the fact that he made a general nuisance of himself. The mother had given up hope of making any relationship with him. He showed no affectionate response. Altough she made several trips away from home, he never asked about her when she was away. Punishment or ordinary methods of correction had no effect. He would "forget" too easily. His behavior in the office was quite infantile, I thought like that of a three year old boy. He showed a

complete lack of appreciation of his difficulties at school and at home. There was no question of some distinct emotional deficiency in his response.

The fourth case is another example of an adopted child, a girl aged nine years and ten months at the time of referral to the Institute for Child Guidance. She was referred for general incorrigibility. She was adopted at the age of seven months into a home in which the foster mother could give little affection, but demanded highly conventional behavior. Before the referral, she had been seen by two psychiatrists, one in consultation and the other for a series of about twelve interviews. She had also received thyroid treatment for a period of time, though our findings showed no evidence of physical difficulty. Our examination revealed, besides the problems for which she was referred, fantastic lying, difficulty in making any friendly relationships with children, and school retardation. The parents noted especially her "failure to profit by experience" and "unresponsiveness to affection." The problem was complicated by the fact that the home was of superior type in a cultural sense—requirements that were too high for a child with an I. Q. of 80. The entire history led to the conclusion that the patient had some inadequacy in her emotional response and was an unfavorable subject for therapy. The parents were, throughout the long contact that ensued, conscientious in cooperating with every therapeutic effort. The patient was treated by the psychiatrist, utilizing chiefly a psychoanalytic method, for a period of two years. The behavior of the patient during the process of over 200 sessions was markedly negativistic. There were some interesting periods of improvement. Nevertheless, the result of the entire therapy was practically nil. At the end of the treatment, the parents were willing to consider another therapeutic adventure before referring the child to foster care. Through special circumstances, it was possible to send the child to Vienna, where she was treated by a psychiatrist of the Adlerian school, with whom she lived for a period of three years. The results were essentially negative; indeed, the child's problems became more alarming because of her greatly increased aggression. She was thereupon sent to her own mother and very quickly got into difficulty because of her incorrigibility and because, somehow or other, she had managed to collect five revolvers. From there she was sent to an orphanage, from which she ran away on two occasions, and then to a detention home, from which the psychiatrist wrote that he considered the patient an excellent prospect for intensive psychotherapy. At the last notation patient was eighteen. It is interesting that the typical attitude of the psychiatrist was that she would respond to psychotherapy. I have cited this case especially to show the failure of psychotherapy to meet these problems.

These case illustrations are given as examples of emotional pathology caused by primary affect hunger of a severe degree. The symptom-complaints are of various types. They include, frequently, aggressive sexual behavior in early life, stealing, lying, often of the fantastic type, and, essentially, complaints, variously expressed, that

indicate some lack of emotional response in the child. It is this lack of emotional response, this shallowness of affect, that explains the difficulty in modifying behavior. The inhibitions to the instinctive impulses, normally strengthened by the response to maternal affection, are no longer in operation. As an instrument in modifying behavior, the power of maternal love may be seen most clearly in life histories where it is absent—a kind of ablation experiment in social life. That the difficulty in these cases is due to a primary affect hunger seems a reasonable assumption, even though not proven by any direct experiment or by statistical checks. Does it follow, necessarily, that any child who suffers complete loss of maternal love, during the infantile period, will develop into a psychopathic personality of the type described? Further, in a number of cases in which a child was given presumably normal maternal love, in the first two years of life, the same difficulties may occur when an attempt at adoption is made at this age. Such cases were sufficiently numerous in my experience to warrant the advice that adoptions be made either in the first year of life, or after the infantile period. It was assumed that when the early emotional attachments were made by the child, as the personality began to grow, a break at this stage caused a situation similar to one in which the child could make no emotional attachment to start with.

There is an interesting bit of evidence on the prognosis in cases of primary affect hunger in a recent issue of the American Journal of Orthopsychiatry.[1] Eighty-one delinquent girls were treated by a combination of social and psychotherapy. Successes and failures were tabulated by follow-up studies varying from one to five years, after discharge from the home. One of the investigators independently analyzed the parent-child relationships and classified them into four groups. The successes and failures were then checked against these classifications. They illustrate a finding already determined in previous studies, to wit that the cooperation of the parent is the most important item in prognosis. One finding, however, is especially striking, namely, that the 17 cases in which there was evidence of complete rejection, showed 100 per cent fail-

[1] F. Powdermaker, H. Turner Levis, and G. Touraine: Psychopathology and Treatment of Delinquent Girls. Am. Jr. Orthopsychiatry, 7: 58 (Jan.) 1937.

ure in response to therapy. This is in contrast with the general result of 50 per cent success for the group. The case examples of complete rejection cited are extreme and convincing.

In contrast with the extreme cases of affect hunger we have, at the other end of the scale, a series of children whose difficulties are solved by the restoration of maternal love. In such cases psychotherapy may be either unnecessary or merely a complementary therapy. There are a number of children who do well with affectionate foster parents, or with a psychiatrist who renders the therapeutic relationship primarily supportive. This type of treatment, to which the name supportive therapy has been given, is a recognition of the fact that in certain cases the child's hunger for love must be gratified. It is recognized that in every therapeutic relationship the patient receives some support of this type (transference) but there are cases in which the treatment must be primarily, even exclusively, supportive; a treatment in which the worker acts *in loco parentis*. Favorable results with such children are often utilized to prove the particular merits of this or the other type of psychotherapy, whereas it matters little what technique is used as long as the child feels loved.

A patient was referred to the Institute for Child Guidance at the age of nine years, with a complaint of enuresis and temper tantrums. A visitor to the foster home wrote a letter to the Institute from which the following excerpt is taken: "He is starved for affection. His mother rarely visits him, although she is urged to do so frequently. When she is there, he acts very infantile, climbing up on her lap, always wishing to be with her, and showing off. Then as time elapses after her visit, he becomes more unmanageable and disagreeable." The history of the case is featured by the child's affectionate response to grown-ups, his making up to any stranger, the explosive and dangerous temper tantrums, and marked jealousy of the other children in the foster home. The "hunger" element in the difficulty is seen in the response to grownups and to the mother, with whom he acts in complete disregard of what is usually a strong inhibiting influence—the presence of other boys. When his mother is about he is always sitting in her lap, he holds his face up to be kissed and puts his arms around her neck. According to the foster mother, he acts in these situations quite like an infant. Though affectionate to the foster mother, he makes no such display with her. The severity of the temper tantrums must be mentioned. On one occasion he tried to break up a game which the other boys were playing. The foster mother sent him to his room, whereupon he tore up the bedding and pulled all the pictures off the walls. On another occasion he attempted to hit a boy with an axe. On another, he chased the teacher and the children out of school.

The patient lived with his father and mother in the first year of life. After the death of the father he was placed in an institution for a year, then for two years in a boarding home, from which he was removed by his mother. He was placed again with the previous boarding mother. He was moved again to a foster home in which he had been living for a year and four months at the time of referral. There are certain elements in the history that indicate a certain modicum of affection from the mother and in the homes in which he was placed. In one boarding home there was an affectionate mother. The foster mother also was affectionate with him. Furthermore, his own mother, though very spasmodic and infrequent in her visits, was affectionate while with him.

In this case, treatment consisted in getting placement with a foster mother who could give him a great deal of affection. There were only four interviews with the psychiatrist. They consisted largely of chats about the foster home. Marked improvement in behavior occurred and continued for two years. A follow-up study made when the patient was twelve years six months old, showed complete cessation of the temper tantrums, good school adjustment, growth in responsibility, though no improvement in the enuresis.

The case described illustrates a very frequent problem for social agencies. A number of cases in the Institute for Child Guidance series show a growing adjustment under the care of an affectionate foster mother. Such therapeutic benefit may occur even in the adolescent group. However, the stumbling block is often the mother of the child, who continues sporadic contact. She visits the child once a week, more commonly once in several weeks, and thereby prevents the building up of a stable relationship with the foster parent. Furthermore, the fact that the child is under foster care while his own mother is still in contact with him, stimulates various fantasies of abandonment, confusion about his own place in the world, sometimes even a confusion of self-identity, often an illusion that the mother who has really abandoned him is a loving and protecting mother. Agencies seem to foster this illusion on the part of the child, because otherwise they would feel guilty of encouraging hostile feelings toward the mother. The mother who has given the child to foster care, yet refuses to give up the child for adoption, is motivated by her feelings of guilt over the rejection and thereby acts as a great handicap to the child's stability. Frequently, also, we have instances in which the mother removes the child from one boarding home, has the child live with her for a week, and then through the agency gets another placement. Because of her own guilt, also, she may find all kinds of fault with different foster

mothers. It is not unexpected, therefore, that a recent follow-up in the case of this patient, now age 18, shows this type of history: discharged from a foster mother to his own mother, back to another foster mother, truancies to his own mother, then placement in a farm school.

In a similar case, presented by Dr. Blanchard at the last meeting of the American Orthopsychiatric Association, the main psychodynamics are clearly discernible. (1) A group of activities representing responses to the primary need. They are manifested in various manoeuvers to hold closely to a person, to win demonstrations of affection, to plead for love, to utilize pathetic appeals and states of helplessness, in order to stimulate a love response from a mother-person. The kissing-bug reaction represents an avidity for physical affection, as illustrated in the previous case, and belongs in this category of responses. So also a number of the whiners and pleaders and naggers for attention, for closeness and for guarantees that the maternal sustenance will never be withdrawn. Out of this group, also, are derived the mechanisms of constant begging for gifts, also of making overwhelming demands from a friendship later in life, to insure against any possible break in the relationship. (2) A group of activities that represent various hostile acts designed to punish the one who denies love and to prevent the possibility of its withdrawal. The mother who has denied or withheld stimulates a hostile rejoinder in the form of wishes for her death, various sadistic fantasies, even threats to her life, also threats of suicide if she will not respond. The conscious level of these performances varies, but they may be overtly expressed. The temper tantrums, possibly also the enuresis may be manifestations in this group, as may all types of "bad" behavior. (3) A group of symptoms that are based on the child's fear of the hostile impulses. These represent the source of the emotional conflicts and neurotic derivatives of the original state of privation. Fear of death is a manifestation. In fact, for every hostile move there is a retaliatory fear. There are a number of interesting derivatives from this state that have to do with the feeling of being deprived, and its consequences. These have to do with various forms of self-pity, the creation in the individual of helpless states, and even depression, but time does not allow these elaborations.

So far I have cited two types of response to affect hunger, one, the extreme instance in which the emotional development of the child has been adversely affected from the start, with a resulting pathology of affect; the other, an instance in which the renewal of maternal love has a successful restorative function. There now remains a large mid-group of cases in which the problems derivative of the early affect hunger are marked by special and usually persistent relationship difficulties. They follow along the lines in which the denials of maternal love and affection are especially marked.

In the last case cited, a boy who made up to every adult, we have an example of what may become a characteristic of every relationship. Such examples are better seen in those adults, whose social life represents a series of relationships with older people, every one of whom is a substitute mother. They may be single or in combination, the point being simply that the patient must, throughout life, be in contact with a person from whom the same demands are made that were thwarted in the original experience with the mother. The life pattern then becomes dependent on maintaining such relationships. When one of them is broken there is a period of depression, or a feeling that " something is terrifically lacking," until another relationship is made. Another type of reaction is seen in the form chiefly of excessive demands made on the person who is selected to satisfy the privations of early life. Such examples also represent a distinctive cluster of cases seen in social agencies, especially in children who have difficulty in adapting to the foster home. The story in typically that the child makes a good impression, the foster parents are delighted, and then, within a week or two, the demands of the child become so excessive that the foster parents are worn out and insist on release from their charge. The problem is always the same—excessive demands for food, for money, for privileges. Attempts to satisfy them end always in disaster. They represent, it seems to me, the child's need of proof that the adult is a loving parent because he satisfies every requirement that is made, also a hostile motive to destroy by getting things out of them. It is as though the child has to repeat the original frustration. A recent example comes to me of a delinquent boy who, in relation with the social worker, tried to get money from her. It was put on the basis that " if you love me you will do this

for me." If the demand was not satisfied, the refrain would be "then this shows that you don't care for me." Every attempt made at giving insight into the relationship failed. The patient showed initiative in getting a job but quit in a short time because he thought he deserved more money, they should give him more time for lunch, etc., etc. Other jobs were terminated for the same reasons. The patient was able to respond only to stern necessity. He was never modified by therapeutic methods.

No doubt there are a number of children who feel a distinct lack that is related to an original privation, who, nevertheless, are in a state of externally good adjustment. Such children naturally are not referred for treatment, since it is rare that a child is not brought to treatment through an adult. There are, certainly, numerous examples of adults, well adjusted according to the criteria of overt behavior, with complaints of various dissatisfactions, chiefly in the form of futility, or depression, that have their origin primarily in affect hunger. How much of the difficulty is related to a true deficiency in the infantile period, and how much is due to neurotic mechanisms is a question that the psychoanalyst is in the best position to solve, but I feel sure that there are numerous instances in which the deficiency is covered by neurosis, and the difficulty mistakenly attributed to the overlying structure. At least, a recognition of this fact will compel a reorientation to the life history.

The responses described seem to pick out special elements of privation in the mother-child relationship. In the social relationship the protective phase of maternal care may be sought; or the giving function in maternal care may be the special point of attack. In others, it may be the mere demonstration of affection, including also genital satisfaction. These elements represent special incompleteness in the early emotional development of the patient and must be demonstrable in numerous phases of the life history, of which this account can only be a rough sketch.

I have tried in this study to indicate certain basic responses to affect hunger, showing a group of cases in which there are pathologic residues due to an extreme deficiency; second, a group in which the restoration of maternal love has marked therapeutic effect; and third, a group which demonstrates specialized difficulties in social relationships that are derivatives of a primary affect hunger.

CHILD ANALYSIS AS A TECHNIQUE IN THE INVESTIGATION OF MENTAL MECHANISMS.

Illustrated by a Study of Enuresis *

By MARGARET W. GERARD, M. D., Ph. D., Chicago, Ill.

Child psychiatry encounters several symptoms which, though very common, have no real consensus of opinion as to cause or treatment. Enuresis is one with which the psychiatrist is constantly confronted, yet as evidenced by the voluminous literature on the subject, our knowledge of enuresis seems in inverse relation to the frequency of its occurrence. Many writers agree that psychological causes play an important rôle, but with a few exceptions offer no real evidence upon which to base their opinion, rather only guesses and generalizations. The literature † shows almost as many causes suggested as articles written. Organic etiology divides into somatic and neurological. Among the neurological causes are suggested: spina bifida;[1] defective cerebral control of the bladder reflex[2] or its disturbance by faulty deep sensation;[3] and, if properly subsumed under this heading, inadequate conditioned reflex development.[4] Suggested somatic causes include: thickened bladder musculature,[5, 6] which prevents adequate distention and, like enuresis, is more common in males than in females; and spasmophilia,[7] associated with increased galvanic response. An equal variety of etiological factors is offered in the psychological realm, including: poor training;[8] a wish for attention, associated with the fear of inadequacy;[9] and a failure to develop responsibility.[10] The psychoanalytic literature considers enuresis as a masturbatory equivalent;[11] or as the consequence of conflict between passive and active wishes;[12] an identification of the male with the female;[13] sexual trauma;[14] or as a desire to return to the suckling stage.[15]

Treatment methods are also manifold, based on the assumed etiology. A drastic suggestion[17] is the use of an occlusive bandage

* From the Division of Psychiatry and the Bobs Roberts Memorial Hospital, University of Chicago.

† No attempt has been made here to review all the literature, which is very repetitious, but some articles are chosen which express the trends clearly.

of adhesive over the genitals to prevent the passage of urine and awaken the child when micturition begins. Of drugs, the most popular is atropine, usually aided by afternoon restriction of fluids and by rectal massage of the bladder.[2] Sunlight and vitamins constitute treatment for enuresis based upon spasmophilia.[7] Frequent awakening of the child to urinate is urged [8] as a means of establishing adequate conditioned reflexes. Various forms of psychotherapy are also offered, such as teaching the child responsibility,[10] and developing self-confidence,[9] and, finally, psychoanalysis.[16]

It is obvious from this review of the literature that there is no agreement yet, either as to the causes or treatment of enuresis-evidence of a serious lack of any real knowledge. In psychiatry and medicine, as in other scientific disciplines, manifold theories betoken lack of satisfactory facts—witness the numerous suggested causes for arthritis and the one known cause of diphtheria.

The solution of such a problem, at least from the psychological angle, obviously requires more facts which can only be obtained by delving deeply into the psychological processes of the individual. Only after the underlying causes and mechanisms have been clearly exposed, may it be possible to correlate them with the manifest symptoms and behavior which they engender. Such a psychic dissection can be achieved with the aid of child analysis. During psychoanalysis, the patient reveals himself far more completely than in other situations. I do not base this statement merely upon a theoretical preconception but upon by own and others' experiences, after using the technique for years.

For many people, "child analysis" unfortunately has become synonymous with the so-called play technique, developed in recent years by several child psychiatrists. To be sure, play is used in analysis as one means of expression, particularly for the younger child. It is generally agreed that play is a means by which the child lives out certain emotional reactions denied him in everyday life, and by which he expresses such concepts of life as he has developed. Since, however, this expression tends to be highly symbolic, it is most valuable not as an end in itself as it is in the play technique of many workers, but rather when it serves as a starting point leading to a verbal expression by the child of its otherwise symbolically acted thoughts and feelings. Since work with the child is carried out in verbal terms, the talking out, rather than the acting out of

attitudes becomes an aim of the analyst. Willingness to talk freely is achieved during the so-called introductory period, which may vary in duration from a week to a month, depending upon the strength of the child's defenses. During this time, because of the analyst's non-critical and accepting attitude, the patient learns that the analyst may be trusted to understand rather than to punish, and that what is done or said during the hour remains confidential. Boldness is thus gained to express thoughts and feelings which were previously carefully guarded from adults. Older children, in the latter part of the latency period, may even willingly lie on the couch while they talk, so that their analysis approximates that of an adult by the free association technique. Younger children, on the other hand, are more apt to talk along with their play or work, speaking of real events and the associated feelings and fantasies, telling stories about pictures drawn, enlarging on fantasies concerning the play entered into, and the like. Interpretation is only given after the material, through its sequential development, is clear and frank, and when the intensity of affect has been decreased by adequate expression in words or actions.

As in adult analysis, the patient's cooperation is greatly increased by illness insight and the wish to be cured but, in contrast to the adult, this is rarely present at the beginning of the analysis of a child. It may usually be secured early, however, by making evident to the child the consequences undesirable to him, of the offending symptom or behavior, and at the same time convincing him of the analyst's desire to help him overcome the source of trouble. The desire for aid in avoiding future pain then leads to talking of subjects which are even able to cause present pain. I shall not discuss further the more detailed technique of child analysis, which is adequately expounded in the literature,[19, 20, 21] but wish mainly to emphasize that, with increasing confidence and during a sufficient time, the child exposes his thoughts and feelings so intimately and in such great detail that one has free access to the essential information concerning the fundamental conflicts and their causes, and to the defense mechanisms developed in an attempt to solve them and which have crystallized into the undesirable reaction formation. Analysis thus becomes the method of choice for studying such symptoms. We need facts on which to base conclusions, and the voluntary self revelation of the patient during an analysis offers

factual material of a richness and surety not otherwise to be secured in the psychic realm.

I have a series of analysed cases of nocturnal enuresis, unfortunately limited to six, but of interest in that certain emotional mechanisms occur in each of them in a characteristic pattern, which is different from the patterns found in children presenting other difficulties. Although only six cases have been completely analyzed, the manifest attitude shown by them has been found equally clearly in 16 others less completely studied. Of the analyzed cases, 3 were boys and 3 were girls; of the others, 10 were boys and 6 girls. Only those patients were selected for study who had developed enuresis after the fifth year and not following the birth of a sibling, thus eliminating children whose enuresis might be based upon slovenly training methods, organic defects or a temporary sibling jealousy. The series was limited, therefore, to cases where the enuresis seemed unequivocally a neurotic symptom.

In all cases, the manifest attitude was quite consistent for boys and for girls but, particularly significant, it differed strikingly in the two sexes. This fact constitutes additional evidence for the psychic causation of this form of neurotic enuresis. The boys' attitude was retiring and self-depreciatory, and fear of physical pain in most of the cases inhibited any form of rough play. They were slow and dawdling in such activities as dressing, eating and getting off to school, and demanded more than the average amount of help and attention in the performance of tasks. None of these boys were doing as well in school as their mental abilities warranted, and there were frequent complaints from teachers that they were inattentive and easily distractible. In ten cases, exhibitionistic reactions were reported, also grimacing, giggling and other non-aggressive ways of attracting the attention of their fellows. There was also a tendency toward evasive petty lying. To this general pattern, there was but one minor exception. One boy, very small for his age, would respond to teasing about his size from older boys by aggressive attacks made in a temper. In all other respects his behavior conformed to the type.

The girls presented an interesting contrast to this picture, appearing much more normal in their manifest attitudes. All were active children, leaders among other girls, independent and proficient in performing tasks. They were successful in school, well

behaved, attentive and ambitious for achievement. Play indulged in with boys showed a strongly competitive spirit, associated with a depreciation of males in general, often verbally expressed. And, finally, they were generally honest and frank in their relations with other individuals. Although the girls, in contrast to the boys, were fearless in daytime activities, both sexes shared a common anxiety, that of nocturnal fears. In some cases, this was evidenced in an undifferentiated fear of the dark without fantasy association. In others, the fear was of attack from some fantasied person, either living or ghostly. Twelve of the children had definite night terrors which awakened them and led them to seek solace from one or both parents. In seven of the cases, these terrors were associated with a remembered recurrent dream, the others were aware of having dreamt but had no memory of the dream content.

In summary, the boys on the whole behaved as if they were inferior to their fellows, whereas the girls behaved as if they were equal or superior to theirs, but in both sexes, a real anxiety expressed itself in nocturnal fear.

In the specific discussion of the analyzed cases, it is obviously impossible to condense into these few minutes the results of several hundred hours study of these children. I shall, therefore, try to document my conclusions with illustrative material from one case of each sex. You will have to accept my scientific good faith that there is adequate evidence for such points as I have to assert rather dogmatically. Each of three boys disclosed during analysis a preponderance of material indicating fear of women as dangerous persons who could injure or destroy him if he were active. The mechanism for overcoming this fear was an identification with the passive woman, and a negation and avoidance of the active rôle of the male. Enuresis thus became part of the passive pattern, urine being allowed to flow uncontrolled and without responsibility for the act. Each girl, on the other hand, presented an excessive amount of material related to the fear of man as a destructive aggressor who could injure her in his activities. She, in turn, avoided the difficulty by denying men their abilities, eliminating them from her existence in fantasy, and yet identifying with the active male instead of the passive female. Enuresis in the girls represented an active soiling rather than a passive flow. Significant, also, is the fact that contrary to the usual findings, no one of these six re-

membered actual masturbation, which leads me to suggest tentatively that enuresis may represent a substitute for masturbation, although further evidence is obviously necessary for such a conclusion. The usual routine material appeared in the course of these analyses, as in all others, these being differentiated by the accent upon one particular developmental conflict and upon the mechanisms used in attempted solution.

I shall briefly describe the relevant material obtained from a 9-year-old boy, material which, in meaningful content though of course not in detailed context, is typical of all three cases. His first transference attitude was expressed as a distrust of me and a veiled fear that I might be dangerous. This was evidenced at first by peeping into drawers and cabinets and behind the couch and chairs for dangerous objects. He asked what I did with the paper knife, with a toy gun (could I shoot him with it), if his hand could be caught in the drawer and cut off, and so on. He complained that some electrical wiring in the room was not safe, that I might hurt someone with it. In attempting to repair an electrical connection of a toy truck, he first asked for help then, with some show of apprehension, refused, saying "you might make it worse, and then it would be ruined." One time, playing with a fountain pen, he squirted the ink, and said it had happened because the pen was broken. He then stated that I must have broken it by pressing it too hard when writing, and explained that it was a delicate object which should be treated gently. One form of play he indulged in was having automobiles collide disastrously. He pretended he was in one car, a woman or a man with a woman in the other; occasionally, a woman was with him. These collisions were always caused by some false move on the part of the woman, and the man was injured. Once the fantasy identified the woman as a false pal who betrayed the patient, because she was really a spy. In this automobile accident, the patient became crippled and he acted out this condition for the rest of the hour by dragging himself around the room with his hands. During this period, he told of a recurrent dream of finding in a garbage pail a dead rat which the maid had caught in a trap and thrown out. This was the recurrent terror dream from which he awakened trembling and, he added, it made him feel as if he himself had been caught and crushed. Telling of this dream followed an unfortunate experience. Coming to my office, he regularly passed a laboratory containing caged cats and frequently stopped to look at them. This day a decapitated cat was on the table, as yet not removed after an experiment. He came to the office trembling and in a rage, accused me of having cut off the cat's head, and wanted to know what other dreadful things I did to animals and people. A little later he created a long fantasy of a vampire, which to him was always a woman, who could bite off parts of his body. He then admitted that his fear of the dark was the fear of such a vampire attacking him. In this same stage of the analysis, he became increasingly critical of his mother. He complained that she punished him for any and everything, that she took away his toys, "monkeyed" with his bi-

cycle and broke it, and interfered with all of his activities. Rather discouragedly he said "The only way to manage is just never to do anything".

Fairly early the patient showed an intense curiosity concerning sexual subjects. He first asked questions voluntarily but tentatively and then, as his boldness increased, disclosed his own ideas on the subject. He (as both of the other boys) believed that sexual intercourse was painful to the man, possibly involving injury to him. The information given by his parents of the sperm entering the egg had been construed to mean that the penis was left in the woman. To explain the fact that a man could have more than one child, he supposed that the organ grew again, but he was in some doubt as to whether this could really happen and, even if it did grow, whether the new organ was as good as the original.

Following the interpretation of his anxieties concerning the destructive rôle of women, and the correction of his fantastic sexual concepts, this boy, as all three, progressed into another stage of positive transference to me. The patient was now friendly instead of critical, was intensely jealous of other patients, drew pictures of hearts inscribed with his name and which he begged me to keep as permanent momentos, and daily brought me gifts. This jealousy, and its implied competition with other patients for my interest, led to another conflict fraught with anxiety. For, if the woman was really not dangerous and the patient accepted the masculine rôle, he was then in danger from the men with whom he competed for the woman. This is the typical oedipus situation, discussed extensively in analytic literature, which represents a general conflict in childhood, rather than a specific one relevant to our present concern.

Of interest in relation to enuresis, however, is the fact that, following the resolution of the anxiety concerning the destructive woman, noticeable changes occurred in the symptoms and manifest attitudes. In two boys, enuresis stopped entirely, not to return; in the third, it changed from a nightly occurrence to a weekly one, when the patient left the orphanage to visit his mother. Three months later, when the fear of his own mother had been more completely worked through and he had returned home to live, the symptom had disappeared entirely. All the boys became more active in play and entered games which they had previously merely observed; their school work improved; dawdling and day dreaming decreased sufficiently to satisfy their parents that they were normal; and night fears were decreased, although they did not disappear until later in the analysis.

As illustrative of the girls all, like the boys, essentially similar, I shall present material from a 7-year-old patient. Her first attitude toward me was one of friendliness and trust, and I became her protector in all fearful situations. The dangerous man came early into her material. A form of play,

rich in fantasies and variations elaborating the same theme, started with a picnic in the country. I was the mother, she the child. There was no father; mostly he was dead, occasionally he was gone for years on a long trip. A dangerous man soon appeared upon the scene, and we fled to a vacant house for protection and had to build complicated barricades to keep him out. He might attack us with knives or injure us by throwing burning brands into the house. A later fantasy, though at the same stage in analysis, acted out in great detail with small wooden figures, was an Indian massacre. The white women were ruthlessly attacked, often scalped, many were wounded and others carried off for further torturing. Of interest was the patient's lack of concern with the fortune of the white men. Once the battle started, they were as if absent, and the total play was concentrated on the fate of the women at the hands of the savage Indians. During this play, she confided that in the dark she was afraid of being attacked by a man with a knife. A second fear was of a cobra possibly hidden under her bed and which might crawl into bed and sting her. Then she elaborated a fantasy, in play with dolls as well as in many drawings, which started in the hospital with a male doctor giving her ultra-violet treatment and causing burns and with a motherly nurse hovering over her, discharging the doctor, and healing her wounds. Incidentally, part of this scene represented a real experience, that of ultra-violet treatments, but she had never been burnt. In a further elaboration of this fantasy, the doctor operated upon the girl and wished to open her whole abdomen. The nurse again scolded and reviled him for his poor surgery and seemed fearful that he might injure the patient beyond recovery. By a skillful kidnapping coup, the nurse then rescued the child from the clutches of the doctor and cared for her at home.

During this period, the patient also told many stories about the stupid boys in school, who couldn't answer questions, and the silly, sissy man who taught gymnasium. She, also, became very critical of the boy whose hour with me preceded hers. In her fantasy, he was a very bad boy who threw stones at girls and chased them with water pistols which shot out poison. In reality, he was a very shy, passive boy. She hardly ever mentioned her father, although she spoke often and freely of her mother, with emphasis on the care and gifts she bestowed on the patient and their easy companionship. Her father was thus mentally eliminated, much as the father in the fantasied picnic party had been physically eliminated. The only comment about her father was that when walking with him, she felt like running ahead and that he talked so much that she was confused and unable to think out day-dreams, as was her usual procedure when with her mother or alone.

Besides eliminating males from her life because of her fear, she disclosed another mechanism, that of masculine identification. This was evidenced in fantasies of being an aviator and surpassing records in height and distance flying, even to circling the earth. She bragged at this time of how she excelled the boys in school in academic achievement, which was true, and in gymnastic achievement, which was not. This she later admitted, but insisted that when she grew older she would be stronger than any man. She stated

then that she could urinate like a man and explained in detail how she had achieved this, during the last two years [and starting about the same time as the onset of her enuresis,] by standing at the toilet. She had practiced sending the stream a long distance and was very proud of her accomplishment. A fantasy connected with urination was the destruction of soldiers in war time by means of a stream of urine. Flying in her airplane, she would herself accomplish this massacre and so become a great hero.

At first the patient had denied sex differences, but later, after the urinary material had been presented, she drew a dog and tentatively sketched in a penis. Then she told very frankly of witnessing a boy's exhibition of himself, and how disturbing this experience had been to her. Then followed questions concerning conception, and in turn her own fantasies on the subject. She had witnessed relations between the parents and interpreted it as an attack by her father upon her mother. She had been given sexual information by her mother, but conceived the act as painful to the woman, the man urinating into her and so burning and injuring her.

As in the case of the boy reported, interpretation of her fear of men, and the correction of her sadistic concept of sex, initiated another phase in the analysis, that of a friendly relationship to men. This was acted out in play, taking the form of the fantasy of two lovers marrying, living happily together ever after, and producing many children. Her enuresis which had decreased during the latter part of the previous period, ceased entirely during this one. She began to go willingly on excursions with her father, which she had previously declined unless her mother accompanied them, and she began to make friends with the boy patient she had so bitterly reviled. Competitive material dropped out entirely from her conversation and play. Similar changes occurred in the other cases at the same stage of the analysis.

In summary, then, we find from the manifest attitudes of these children evidence of passive male and of active female behavior. In analysis, we find that these attitudes are techniques of defense against an anxiety; in the boy, a fear of the woman who becomes dangerous if he is active and, in the girl, a fear of the active destructive male. Passivity thus protects the boy from danger, and enuresis is one passive symptom of the total constellation. Activity, similarly, protects the girl from that passivity which exposes her to the attack of the man, and enuresis is also part of her active constellation, since urination is conceived by her as an aggressive destructive process. And for both, as earlier indicated, the symptom may represent a masturbation equivalent. We do not yet know why this major conflict is expressed by means of the urinary system, but that it is so expressed is shown unequivocally in the analytic material, and particularly by the disappearance of the symptom with the elucidation of the conflict.

Obviously more cases are needed to place these observations on a firm footing and obviously the analysis leaves much yet to be explained, thus the specific situations which created this particular fear, and the choice of the urinary system for its expression. But, so far as any conclusions on a limited number of cases are justifiable, the rich material of the whole analytic procedure and the sharp change in enuretic and related symptoms at a given stage in the child's understanding warrant the conclusion that the type of enuresis investigated in this study is one symptom of an anxiety neurosis, the major cause of which is a fear of the opposite sex.

CHILD PSYCHIATRY.*

By JAMES S. PLANT, M. D.,
Director, Essex County Juvenile Clinic, Newark, N. J.

In relating child psychiatry to adult aspects of the subject, this paper deals with shifts in emphasis rather than sharp and fundamental differences. Nor does it attempt to enumerate all of those points at which there are these differences in emphasis. It merely indicates three points at which child psychiatry has a considerable contribution to make to the adult field.

It is apparently the stylish thing to say that adult psychiatry deals with more complicated and difficult problems—that child psychiatry, in getting the problem early, gets it in a simpler and more easily modified state. This is not a correct statement of the situation. It is true that as one grows older he more and more personalizes the problems of his environment. Indeed, the process of growing up is largely one of bundling up into one's own personality the problems and tensions which belonged to the adults who surrounded his childhood. Child psychiatry does not deal with simpler problems but rather with problems in a different locus. Its diagnosis and therapy lie largely in the environment.

Because of this personalization, adult psychiatry is preoccupied with relatively dramatic and insistent difficulties. Whether the matter involves the pattern of a whole mode of living (as in dementia præcox) or an apparently isolated, specific complaint (as in some bizarre obsession), the psychiatrist feels that he is dealing with a situation that itself has drive and some sort of unity. In this field, we are dealing with relatively crystallized phenomena which seem to "come from somewhere." Thus diagnosis and nomenclature in the adult field have been in terms of the result produced—in terms of the situation which brings the patient to the psychiatrist. To the extent that psychiatrists trained in adult work have gone into or influenced child psychiatry, there has been this same effort

* Read, as part of a symposium on Child Psychiatry, at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

CHILD PSYCHIATRY.*

By JAMES S. PLANT, M. D.,
Director, Essex County Juvenile Clinic, Newark, N. J.

In relating child psychiatry to adult aspects of the subject, this paper deals with shifts in emphasis rather than sharp and fundamental differences. Nor does it attempt to enumerate all of those points at which there are these differences in emphasis. It merely indicates three points at which child psychiatry has a considerable contribution to make to the adult field.

It is apparently the stylish thing to say that adult psychiatry deals with more complicated and difficult problems—that child psychiatry, in getting the problem early, gets it in a simpler and more easily modified state. This is not a correct statement of the situation. It is true that as one grows older he more and more personalizes the problems of his environment. Indeed, the process of growing up is largely one of bundling up into one's own personality the problems and tensions which belonged to the adults who surrounded his childhood. Child psychiatry does not deal with simpler problems but rather with problems in a different locus. Its diagnosis and therapy lie largely in the environment.

Because of this personalization, adult psychiatry is preoccupied with relatively dramatic and insistent difficulties. Whether the matter involves the pattern of a whole mode of living (as in dementia præcox) or an apparently isolated, specific complaint (as in some bizarre obsession), the psychiatrist feels that he is dealing with a situation that itself has drive and some sort of unity. In this field, we are dealing with relatively crystallized phenomena which seem to "come from somewhere." Thus diagnosis and nomenclature in the adult field have been in terms of the result produced—in terms of the situation which brings the patient to the psychiatrist. To the extent that psychiatrists trained in adult work have gone into or influenced child psychiatry, there has been this same effort

* Read, as part of a symposium on Child Psychiatry, at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

at looking at the child's problem in terms of its "coming from somewhere." However, the real contribution of this field of child psychiatry will lie in the extent to which it preoccupies itself with social or personal stresses which are thought of as "leading to somewhere." This, then, is a second contribution made by child psychiatry—its interest in the cultural and personal loads placed upon persons—its emphasis upon the stresses which lead to maladjustment, rather than in the maladjustment which has been the final outcome of certain processes.

The third alteration in emphasis which is developing in the field of child psychiatry, has to do with the inter-relationship of causal factors. It would be ridiculous to claim that, in the adult field, such a recognition could not occur or that there are not psychiatrists in that field who are not fully aware of the fact that a trait or phenomenon has importance and reality (in respect to a certain result) only in its relationship to the existence of many other traits or phenomena. I could illustrate with the supposition that we now are casting six dice. Suppose that one comes up a one, one a two, one a three, one a four, one a five and one a six. About this, it is very obvious and very tempting to ask two questions; (1) To what total do the six dice add; and (2) which of the dice are the important ones in making this total of 21. A great deal of the research in the adult psychiatric field has busied itself with precisely these two questions. One must admit that a fair fraction of work in child psychiatry has been built on these same questions; volumes have been written on the causes of delinquency, the causes of enuresis, the causes of temper tantrums, etc. Yet it must remain true that because the locus of interest is so much more diffused and because it is more in a number of initiating factors than it is in a relatively simple and dramatic result, it will be in the field of child psychiatry that we shall see that any so-called "causative factor" is such—and has power as such—only in its relationship to other factors. One hopes for the time when we shall cease attempting to relate delinquency, neurosis or psychosis to race, religion, chemical compounds, delinquency area, temperament, whatnot. Each of these factors exists, is important, has reality only as one of the parts of a picture—and to extract it from that picture for the sake of constructing statistical tables, is to rob it of its meaning.

The following cases may in some ways illustrate these three points:

John West was 10 when we first saw him. He was a somewhat tense child, the middle of three in a professional family of considerable means. His older brother, 12, was a rather constant companion, very largely because the parents had thought that their children "should grow up together." The father, an unusually gifted man, "did lessons" with the two boys where he found John the quiet, studious interested member of the pair. Indeed, John played very well with his older brother and there was every superficial appearance of deep regard and mutual admiration between the boys. We were asked to see John on account of his tenseness, but chiefly because he wet and soiled himself. These last activities were particularly annoying as they seemed to come chiefly at times when the child was dressed for some particularly important or festive occasion. The family simply could not accept our recommendations that the two boys build up two entirely different play groups, that one of them soon be sent away to private school and that the father cease carrying on the lessons with the two together. For two years the family did nothing, put up with the inconveniences that John caused and occasionally tried one or another trick advised by kindly neighbors. At 14, the older boy went away to school. Within one week, John's tenseness disappeared and all soiling and wetting disappeared. The change has continued over the last seven years.

Anna was nine when we first saw her. She was in the sixth grade in school where, studious little soul, she was getting good marks. She was fond of school and was much the pet there. We found an I. Q. of about 130 and convinced ourselves that purely within the area of academic intelligence, the youngster could easily cope with her classmates. She was brought to us by her parents who worried about her nail biting, her high pitched voice, her obvious tenseness and rather fitful sleep, and because she was showing an increasing vulnerability in the gastro-intestinal system, with scattered periods of nausea, vomiting and diarrhea. This was a hard case to handle because the youngster had attuned her interests and games to an 11- and 12-year level, and looked upon nine-year occupations as babyish. Anna is an only child and her family valiantly followed us through a pretty difficult program. They moved to the country, they took Anna out of school, the mother went with her once or twice a week to the museums, etc., of New York, they subtly led her to form collections of her own. Companionship with other children was not forbidden but kept at a minimum. Great care was taken to keep the *depth* of interests near the nine-year level, and to substitute breadth and number for what the youngster was otherwise missing. During the next year, a decided improvement in the symptoms appeared. The year after that Anna was reentered in the sixth grade. She is still with slightly older children and even now (three years later) she is not an entirely placid, easy-going type of individual. Nevertheless, she is extremely happy and popular with her new group and the decrease in her "nervousness" has been marked enough to make her family and neighbors consider her as cured.

Bernard we saw two years ago, when he was 11. He is the second of two boys and is two years younger than his brother. That year, the boys were in separate schools (the brother being in junior high) but they still had their play-life entirely together. Indeed Bernard was a good athlete and was a prized member of the various teams his brother played on. The only difficulty was the existence, for four years, of what appeared to be typical grand mal attacks. Bernard was referred because papers had been partially completed for his entry to the State Colony for Epileptics and it was expected that I would act as the second committing physician. There was much in the picture that didn't look like epilepsy. In fact, nothing belonged to that diagnosis except the admittedly typical character of the attacks. Here, again, was a tough job but the family, the school and the recreation leaders fully cooperated. The boy was made an important cog in teams of boys of his own age and younger. A splendid job of building athletic interests at his level was done. About a month after we first saw the boy, there was another typical attack—loss of consciousness, loss of sphincter control, clonic convulsions. Since then there have been no more attacks.

Kenneth, we saw a year ago when he was six and in the first grade. His teacher was at her wit's ends with this restless, jumpy little youngster's disruption of her class routine. Kenneth has a very high I. Q. and had had his play-life entirely with nine-year-olders. He never sat still, his family being quite as distracted over his constant activity as was the school. Kenneth lived in a tight little community where we felt hopeless about changing his play group. Consequently he has been at a small school near enough for frequent parental and home visits but so constructed that he could not compete with the attention span and emotional interests of those three years older than he. Obviously this has required all sorts of resourcefulness in adequate substitution. Let no one mislead himself as to the difficulty of keeping busy these children who have been artificially keyed up to a high pitch. Actually to-day it would be hard to recognize Kenneth. He is still intelligent and alert but he is comfortable and, for the most part, relaxed. He can quietly interest himself for long periods at his games and is playing increasingly with children of his own age. One sees no reason why one more year of this sort of treatment will not solve the situation.

To these four briefly described cases, I should like to add one more. For it, I shall ask each of you to go back to your neighborhood to pick out a boy or girl anywhere from 6 to 14 who is habitually playing with and competing with children some two years his or her senior. I suspect that each of you knows such a child who is not showing, so far as you can discern, the slightest sign of unusual or disturbing tension under this arrangement. I can't deny that *possibly* those children would be even happier and better adjusted if they were not playing with the older ones.

I confess that my naive mind prefers to accept the situation as being often one that apparently produces no outward symptoms.

This paper, while it has not endeavored to present anything that is particularly new or startling, has attempted

A. To emphasize the pressure which we place upon the child rather than the results produced.

B. To indicate that these pressures are dynamic and fruitful only as they are related to other conditions—that there is not any one to one relationship between a given cause and effect.

C. To indicate that nomenclature in child psychiatry, if attempted at all, must be in the field of the types and strengths of the pressures rather than in terms of the symptoms or conduct-picture with which the child comes to the psychiatrist.

D. To call attention to the possibility that the point of break (or presenting symptom) is rather a matter of chance or is, at least for the present, unpredictable. This strengthens our belief that if we are to extend our nomenclature to the field of child psychiatry, it probably must be built in terms of the social problems which the child has to solve rather than in terms of the way he has solved them.

E. To point out that the significant forces are not personalized at this level; that the matters of chief concern lie as much or more outside of the child than within; that while obviously different children react in different ways, we are still at the place where environmental changes can clear the situation which does not go on dynamically developing within the individual.

F. To suggest that these same considerations may, in time, extend into the field of adult psychiatry, to mean that our nomenclature will shift to the cultural pressures involved rather than the symptom pictures shown. From the point of view of therapeutic measures this seems to me a most hopeful trend, though the factor of high personalization of cultural pressures may always mean that cultural changes cannot produce anything like the patient changes which one gets in work with children.

SOME THERAPEUTIC PRINCIPLES APPLICABLE TO PSYCHIATRIC WORK WITH CHILDREN.

By FREDERICK H. ALLEN, M. D., Philadelphia, Pa.

In this paper I would like to give further definition of some principles found applicable to therapeutic work with personality problems in children. This paper will be limited to a discussion of work undertaken directly with the child, and will not attempt to deal with other aspects of treatment that usually accompany and supplement direct work with the child.

The phenomenon of change brought about by the differentiating process of growth is the aspect of the life which always will stir the interest of the student of human behavior. The multitude of influences impinging upon the developing child, with the endless varieties of individual responses to these stimuli provide the constantly revolving stage upon which we can view the drama of human growth with the emergence of individuals, each acquiring through their own experiencing different characteristics.

The psychiatrist working with children has a special interest in the phenomenon of change when he enters the reality of the child's life, through assuming a responsibility for helping him through some of the turmoil emerging out of the growth process. To understand how this special and purposefully undertaken relation can work to influence change in a child, is important to those doing therapeutic work in this area of psychiatry.

In this brief statement, I want to discuss how therapeutic work can be understood as having real meaning for the child when we can frankly accept this new and unique relation for what it is. It is an experience in the child's present and not in his past; it deals with the child as he is, with his strength and his weakness; and the main value may be around helping him to make more creative use of his capacities to establish this new experience, as a start toward more balanced development. While therapy is undertaken around a child's difficulty, it is carried on and built up by what he can put into it. It is related to his strength and is not built up around his weakness and the primary interest is in what he can do and not in what he cannot do.

In the earlier days of psychiatric work with children, little recognition was given to the fact that a child is an active participant in his own growth and therefore a participant in determining the nature of his own reactions. When children were brought into therapeutic procedures it was more for the purpose of fact finding and formal diagnosis than for direct help. Influences designed to help the child were seen as being applied *to* the child. Parents were accepted as holding the whole responsibility of the child; and what he became, good or bad, was thought to be determined by what they did, and that change would follow as their attitudes and feelings were modified.

The therapeutic work done directly with the child frequently was an extension of this principle, with the emphasis on the external influence the psychiatrist brought to bear on the child in the form of direction and explanation. The therapist assumed the heavy share of responsibility for whatever change took place and the child had only to listen, to believe and follow directions. Therapy, both for the child and parent, was seen as process of synthesis through giving. Kanner gives a good description of this externalized type of help when he states this conception of direct work with the child.[1]

> For our purposes and for anyone trained to deal soberly with the concrete facts in the matter it seems sufficient to know that the patient (child) listens to us attentively, understands what we have to say to him, is capable of accepting facts which have been furnished by himself, by his parents, and by an objective examination and is willing to participate in an arrangement which promises to relieve him of his difficulties.

One fact that characterizes the therapeutic relation is that it is in the present, and around the self of the child that has emerged up to that point. Whatever the therapeutic philosophy that is applied, it is around the present child that it works. In recent years there has been considerable emphasis on the genetic approach to the child. The child of the present is approached and understood through the past. Emphasis gets placed on what he has been, as a way of helping him to a healthier way of being what he is now. My own feeling is that such an approach which seeks to use a present relation

[1] Kanner, L.: Child psychiatry, p. 122-123. Springfield, Ill., Charles C. Thomas, 1935.

to reactivate earlier periods of life and interpret present phenomena in terms of earlier experiences and relationships, may and frequently does complicate the growth problem of the child by rooting him more to the very past that aids him to avoid the realities of present living.

The therapist, with this historical approach, will be less sensitive to the meaning of what the child is able to do or what he is doing with the self that has emerged from the past in the relation he has with that child, because what the child does is immediately translated into history. The interest is not in what he *can* do now, but more in what he is unable to do because of earlier experiences and deprivations.

A good example of this strictly genetic approach is given by Bernfelt when he says: [2]

"A phenomenon is not comprehensible to a psycho-analyst unless he can describe how it has come about." He applies this when he says further: "As analysts we dare to 'accuse' a child who is industriously at work on his geography lesson as performing a masturbatory act. We are justified in this manner of speaking if we can show that the particular way in which the child sits quietly and devotes himself to his geography lesson, is derived from actual masturbatory activities that have been combated, changed, suppressed and sublimated." This is another way of stating that nothing is ever what it seems to be, and when that is believed and applied as a cardinal part of a therapeutic approach, naturally the activities and feelings will be taken out of their present setting and given a meaning in terms of a hypothetical and theoretical historical self.

It is interesting to go outside our own professional field and find this critical statement about the historical method. Teggart [3] defines the historical method "as that procedure of explaining or elucidating a given present by stating its antecedents in time," and then states:

"Preoccupation with original documents brings with it a sense of security, a conviction that work based on primary materials must be necessarily sound and enduring. Hence the academic historian holds to the belief that having discovered the facts all that

[2] Bernfelt: Psychoanalytic Psychology of the young child. Psychoanalytic Quarterly. Vol. IV, No. 1, p. 8. Jan. 1935.

[3] Teggart: Theory of history, p. 25. New Haven, Conn., Yale Press, 1925.

remains to be done is to state what he has found without prejudice or bias. It is not to be wondered at, that having adopted this view he should be nonplussed, and eventually irritated when it is pointed out that the end of this effort is a composition of a narrative marked by partisanship and emotion." He further concludes [4] "As a consequence academic history ends in narratives which embody for each generation the human interest of the past, not in statements as to how things work in the word of men." This statement, when applied to the study of human behavior, can have considerable validity as a criticism of the historical approach as the only way to understand present phenomena in human beings.

I have quoted these references for the purpose of giving sharper definition to some therapeutic principles which have grown from a point of view which seeks to begin where the child is in his own development, and help him to find in the self that has emerged, capacities to meet the turmoil of his own growth, irrespective of what has gone before.

From the point of view of the child, the really important thing is what he can feel himself to be now. That is where he will begin irrespective of the point of view of the therapist. Therefore, the basically important goal of therapeutic work with the child is to help him find from this experience, qualities which he can accept as his own and which he can use more creatively in establishing himself in this new and self-limited relation. This can provide a growth experience for the child and offers possibilities for self discovery. It becomes a growth experience when this experiencing of himself is around the person of the therapist. It is the immediacy of this relation that makes this possible. The therapist is not a part of the past, although the child may bring in the turmoil emerging from the past. But in doing this, disturbed feelings no longer belong to the past. They are in the here and now and can be dealt with by both child and therapist in terms of what feelings are now rather than in what they have been.

Objections have been raised that feelings dealt with in these terms represent only superficial and obvious evidence of the child's difficulty and therefore have only temporary value, while the deeper turmoil of the child remains untouched. There is the future ob-

[4] *Ibid.*, p. 75.

jection that only children with superficial difficulties can be treated this way and the more seriously involved neurotic child will need what is commonly called "deep therapy," which means that these feelings must be experienced around relationships and events in the dim and inadequately forgotten past. Anything short of that is distrusted.

My own experience in dealing with seriously disturbed children has led to the opposite conclusion. Such children are rooted to the past and their behavior serves as an important and effective means of avoiding the realities of the present. The more difficult and disturbing task, but at the same time one that can have deeper meaning, is when the child can allow that turmoil to be experienced as a part of this immediate situation in which he finds himself. This is where the psychiatrist has entered the life of the child to help him create an immediate relation that develops its own realities with values and limitations.

For example, a 13-year-old girl with a great deal of neurotic fear tries very hard to keep these fears on childhood events and then fear tenaciously clings to childhood and to her mother as a symbol of it. She begins to do more things on her own and among them was coming to the clinic by herself, a significant and courageous step because it signified more willingness to give up childhood. Around the doing of this, real fear emerges. Helping her to understand and deal with this fear in terms of her present doing, disentangled from all the disguises, had deep and real meaning for this child. She was finding her neurotic fear an effective shield against anything immediate. The real fear came out as she faced her own growing up and her therapeutic experience was a spot where that was beginning to happen. Why do we have to evade the growth value of this immediate experiencing by taking the feeling out of its present setting and pushing it back where it does not belong?

I want to illustrate some therapeutic values that can accrue when the orientation is to the present child, by discussing how some children can focus the fears which have made therapeutic assistance necessary in the relation a psychiatrist can have with a child.

Two aspects of fear must be kept in mind—one is concerned with the causes and the other with the value of fear as a means of control.

Some fear is inherent in the growth process because the nature of growth involves leaving the old and undertaking the new. Fear not only emerges out of the growth process, but may provide the

child with a powerful means of clinging to what he has and resisting the very thing that induced fear, i. e., growing up. Therapy oriented to a genetic approach will, in its determined search for etiological factors, overlook the ways in which fear has come to have value to the child, particularly in the therapeutic relation itself. A valuable illustration of this is provided in Freud's account of the phobia in five year old Hans,[5] the article which has been referred to as the corner stone of psychoanalytic therapy with children. Hans was fighting against any acceptance of his own difference from his mother because that meant growth and leaving her. The mother was making a determined effort to prevent him from growing up and Hans was caught in a dilemma. Fear in the form described emerged as his own growth created an awareness of his own differences, i. e., he had a penis and his mother did not. This organ became the symbol of badness, partly through the handling of his masturbation, but mainly because the penis was the evidence of being different from his mother. Horses seemed to symbolize the bigness to Hans which his own natural growth was creating and his fear was centered around horses. As efforts were made to get at the etiology of his fear, no attention was directed to the obvious determination of Hans to cling to the idea of fear because it had become such a valuable way of controlling his own growth and preventing further separation from his mother. An example of this is provided when his father, who was conducting the therapy said: "As long as you come into our room in the mornings your fear of horses will not get better, and Hans replies in a defiant mood ' I shall come in all the same even if I am afraid.' So he will not let himself be forbidden to visit his mother." I might add, nor would he let anyone, at that time take the fear away because through fear he was in control.

I want to illustrate further some of these points by a brief reference to one aspect of treatment undertaken with a six-year-old boy around an overwhelming amount of fear he was having in most of his life experiences. This behavior was exaggerated particularly in his relations with his mother, who constituted his main source of safety following the death of the father. He was determined not to grow up and the fear which had emerged as he had to meet

[5] Freud: Collected papers, vol. III, p. 189-190.

new experiences, had become his main weapon to fight against leaving anything or letting anyone leave him. I want to give some details of the first interview with this boy because it illustrates one important point of this paper.

He was tense and fearful when his mother introduced me, but he handled this fear by an exaggerated assertiveness in his first hand shake. It was not a friendly shake, but an aggressive pulling of my hand. He left his mother in the waiting room and, when alone with me in my office, he planted his widespread feet firmly on the floor and said, "I knocked you down, I can do it again and I can bring my rope in here." There was a great deal of fear behind this but, instead of recognizing his fear, I joined in and supported him in his verbal statements of aggression. He looked around the room and said, "This all you got here?" and again I joined him in criticizing the place. His name was John but was known as Jack, a name I used. This was too familiar and he responded, "Don't call me Jack, I slap kids if they call me that." I smiled and said, "I guess I had better call you John," and then asked if he knew my name and he blurted, "I will call you anything I want."

Gradually, there was some relaxation but he made it clear that all he was doing was because he wanted to. As he started to play, he said with great determination, "Don't you forget. I am coming in here next Monday" (his correct time), and when I responded, "Would you like to come?", he could not allow the coming to be on liking it but only on controlling it, and said with great emphasis, "I am coming, you better expect me."

He continued belligerent in his feelings and words, but not in action. When he continued critical of everything, I commented, "There doesn't seem to be anything here you want." He replied, "I want the whole place," and referred to the toys as "my toys." I was included in this sweepingly possessive use of liking. What he liked he immediately wanted to own.

In the middle of the hour, I asked what he thought of the idea of coming to see me and he again asserted, "I came because I wanted to," and gave a fictitious story of getting into the car a half-hour ahead of his mother to prove he had come without being asked. He was proving he could be strong enough to keep from submitting to any desire I might have for him.

The natural limits of the hour became apparent when I commented he had 15 more minutes, to which he responded, "Is that so? I think I have 45 and you'll clean this place up when I leave." This was the first assertion around something much more real and he was worried as he watched my face. As I smiled, he relaxed into his first smile of the hour and with more gentleness he asked, "Is this too much noise?" I commented, "What's the trouble, don't you like noise?" He said sure and I told him to make all the noise he wanted. Immediately he assumed control again and said, "I am making noise."

A few minutes later he asked with more acceptance, "How much time do I have?" I told him and he said, "I think I will come in here every day." When I commented, "You are a little upset because you can't," he said with

characteristic force, "But I can." He remained uncertain about making noise and asked, "Are you allowed to make noise in here? Now don't tell me no lies." I responded in terms of his feeling about me and commented he wasn't sure of me yet and he replied, "I am going to make noise."

There followed some determined statements about taking my possessions, and when I commented, "You feel you own what you want," he asserted, "I get what I want." The hour ended in this interesting way. He started putting things away without any suggestion from me but said, "I will put these things back the way I want to and when I get these toys away I am going to leave all by myself," and he did.

I have used this initial interview with a six-year-old to illustrate an important therapeutic principle. Emphasis in this paper has been placed on the value the therapeutic relation itself has for helping a disturbed child to find qualities in himself he can accept as his own and use to establish himself in this new experience. This boy, in his first and crucial hour, found a way of handling his fear by a vigorous assertiveness that was foreign to anything he had shown before. This was a start for this boy to find both the values and limitations of this power in the one relation in his life that had not been built around fear. Strengthening what he had found and helping him live in this relation with the limitations and uses of this more active, alive side of himself, seemed more important than focusing on his fears and searching with him through the recesses of the past, for the specific experiences around which the fears started.

I wanted to help this boy leave the past and deal with the self that had emerged from it. His difficulty was around not being able to give up infancy and he had found fear, which had emerged out of the separating nature of growth, a valuable means of controlling his own growth. He did not have to go back into his historical past to find the cause of his fears as this new experience created its own opportunities for fear and for finding what he had in himself to deal with that fear. As he was able to accept these qualities as his own and use them to bring himself into a more friendly and growing relation with his own reality, he was able to give up his fear as being unnecessary and to resume his growing up in a more balanced way.

Ending a case like this brings in another important element. This boy was moving toward such an easy acceptance of himself. He was quite a different boy and became aware of a desire to end. One

day, in his play, he painted a " for sale " sign and shouted out of the window to find a buyer. When I commented, " You are about through with this place," he denied it at first but later was partly able to accept it. In the next hour, he decided there was not much to do and left 15 minutes early. Everything he was doing with me and in his behavior outside indicated he was about ready to leave after 12 interviews.

But anticipation of leaving and my discussion of it with him recreated some fear and he reacted with a determined statement that he was never going to leave and would come until he was grown. Two alternatives were possible. One, to see the fear as evidence of needing more help and to prolong ending to deal with the feeling that the thought of ending stirred up. This would create a dilemma, because fear again would become valuable as a means of perpetuating a relation he found hard to leave. If he was allowed to continue he would be caught with the fear and this could go on indefinitely. The second alternative involves recognizing that it is just as important therapeutically to help a child to end treatment as it is to help him to begin it. This involved dealing with his determination to avoid taking any responsibility for the ending in spite of his evident desire and readiness to end. This was done and while he continued to make statements that he would come for another year, he did allow himself to end around his own desire, and did so without fear.

This important principle should stand out in therapeutic work with both child and parent. Help must be directed to the more positive aspect of the self, with the interest focusing on what can be done rather than on weakness and what cannot be done.

A child will present a great deal of turmoil in one way or another and may present a picture of needing a great deal. But where the focus of therapy can be around what he has, we can be more sensitive to the ways that the child can begin to bring out and use those positive qualities in this immediate relation to deal with his difficulties. In the case discussed, the important thing for the child was helping him to use qualities in himself to handle his fear as he established himself in this new relation. This he was able to do and, in so doing, moved rapidly toward a different feeling about himself in the realities of his own life.

CONCLUSION.

Therapy emerges from this unique and limited growth experience for a child because it is one established around his own feeling and with a person who has no goal other than helping him to a more creative use of his own potentialities in the realities that the relation itself creates. Through such an experience, he may gain a more positive acceptance of the self that is his and a capacity to relate that self to others and to the responsibilities which growing up involves. Therapy can held a child to catch up with himself and bring himself up to date. If he can do it, therapeutic work has helped him to achieve an important step in his own growing up.

AN EVALUATION OF THE TREATMENT OF PROBLEM CHILDREN AS DETERMINED BY A FOLLOW-UP STUDY.

By HOWARD W. POTTER, M. D.,
AND
HENRIETTE R. KLEIN, M. D.,
New York, N. Y.

Since 1930, the New York State Psychiatric Institute and Hospital has maintained a ward service for problem boys and girls under the age of 13 years. It has been the policy of the Institute to admit children to this service whose problems were of such a nature that they could not be cared for at home and treated in an out-patient department. Extremely difficult behavior, advanced neurotic symptomatology or psychotic manifestations were the usual reasons for admission; only an occasional patient was admitted for purely diagnostic purposes.

The children's service of the Psychiatric Institute [1] provides the problem child with a temporary escape from undue stresses, strains and insecurities which beset him in his home, his school and his neighborhood; and affords a tolerant, understanding environment which exacts a reasonable compliance to a few simple rules and regulations. The idea of treatment is uppermost and is regarded as a 24-hour-a-day problem. Treatment is widely conceived and is carried out through re-educational work, school room instruction, modified occupational therapy, dramatics, weekly trips throughout the city for diversional and educational purposes, collective games and parties, etc. Many of the children have extensive psychotherapeutic sessions [2] with a psychiatrist and the key person in the family has continued interviews with a psychiatric social worker throughout the child's stay in the hospital.

[1] Potter, H. W.: A service for children in a psychiatric hospital, Psychiatric Quarterly, 8: 16-33, 1934.

[2] Potter, H. W.: Psychotherapy in children. Psychiatric Quarterly, 9, pp. 335-347, 1935.

All children included in this study had been discharged at least a year prior to the date of the follow-up contact. The follow-up study consisted of a personal interview with the parent and child by the psychiatrist, and a visit to the home and school by a psychiatric social worker.

Inasmuch as social maladjustment or neurotic symptoms usually bring the problem child to the attention of the psychiatrist, these were used as a basis for evaluating the condition of the patient as observed at the follow-up contact. If the child was getting along well at home, in school and in the neighborhood, and was free from symptoms, his adjustment was recorded as *satisfactory;* otherwise, *unsatisfactory*. In certain instances, some of the children showed an optimum improvement but their own constitutional limitations (mental defect) or the limitations of their environment (a psychotic mother) were of such a nature that even with their optimum improvement they were unable to attain a satisfactory level of adjustment.

In order to compare outcome with causative conditions and clinical reactions, the cases were classified as follows:

I. The Organic Reaction Group (including idiopathic epilepsy):
   A. Idiopathic epilepsy.
   B. Mental deficiency.
   C. Juvenile paresis.
   D. Behavior problems secondary to organic conditions.

II. The Situational Reaction Group:
   A. Personality and habit problems.
   B. Conduct disorders.
   C. Psychoneuroses.

III. The Psychotic Group.

THE ORGANIC REACTION GROUP (INCLUDING IDIOPATHIC EPILEPSY).

Present social adjustment.	Idiopathic epilepsy.	Mental deficiency.	Juvenile paresis.	Secondary behavior problems.	Total.
Satisfactory	3	5	0	2	10
Unsatisfactory	6	22 *	7	19 †	54 ‡
Total	9	27	7	21	64

* 2 dead. † 1 dead. ‡ 3 dead.

Idiopathic Epilepsy.

These patients were admitted in order to evaluate the nature of their convulsive seizures. In some, a primary psychogenic factor was suspected but was not supported by further study. The three patients who are making a satisfactory social adjustment had only petit mal phenomena and although the petit mal seizures persist, they are not of sufficient gravity to interfere with the child's adjustment.

Mental Deficiency.

The mental defect in these 27 patients was evidently congenitally determined. In the older patients, the mental deficiency was associated with behavior disturbances and in the younger, with schizoid traits. Twenty-two were of moron level and five of the imbecile grade. Only five of the total group were making a satisfactory adjustment and were regarded as well adjusted defectives at the time of the follow-up study.

Juvenile Paresis.

In each of these cases the clinical course of the disease was arrested but no remissions occurred. All were in an advanced stage of the disease at the time malaria and tryparsamid therapy was instituted. None of the seven in this group show a satisfactory social adjustment.

Secondary Behavior Problems.

Cases in which the behavior problem, characterized by uncontrollable aggression, was a direct expression of a demonstrable physical disability or organic condition. With one or two exceptions, these patients were admitted for diagnostic study and observation. In 15 of these patients, the behavior disorder was associated with encephalitis; in two, with post-traumatic brain changes; in one, with deaf mutism; in one, with a mild hydrocephalus; and in two, with dyspituitarism. The two patients in this group making a satisfactory social adjustment are the deaf mute, who is now a happy, contented child attending a school for deaf mutes, and the patient with hydrocephalus.

THE SITUATIONAL REACTION GROUP.

Social adjustment.	Personality and habit problems.	Conduct disorders.	Psychoneuroses.	Total.
Satisfactory	14	26	15	55
Unsatisfactory	11	25 *	6	42 †
Total	25	51	21	97

* 1 dead. † 1 dead.

These 97 children were free, so far as an examination could determine, from any organic or somatic condition which might have furnished a basis for their personality or behavior problem. Sixteen of these patients were in the hospital for a period of less than three months and were removed against advice before a reasonable period of treatment had transpired. Seventy-two spent from 3 to 12 months in the hospital and nine remained for well over a year.

Personality and Habit Problems.

Enuresis, masturbation, faulty habits of eating and sleeping, mild temper tantrums, timidity, shrinking from social contacts, speech disturbances and non-aggressive oddities of behavior which appeared to be expressions of larval forms of psychoneurotic or schizophrenic reactions. Here, the successes and failures, in terms of present social adjustment and presence or absence of the symptoms which necessitated hospitalization, are about equally divided, 14 being considered satisfactory, and 11 unsatisfactory.

Conduct Disorders.

Problems of aggression against persons and property, destructive and belligerent rages, running away from home and school, stealing, setting fires, sadistic and cruel treatment of other children, rejection of authority, incorrigibility, disobedience, etc. Of these, 26 show satisfactory social adjustment, and 25 unsatisfactory.

The successes and failures are thus about evenly divided. When grouped according to intellectual equipment there was not a sufficient number in any group to draw any definite conclusions as to the effect of the intellectual equipment on ultimate adjustment. However, the distribution suggested that of those with superior intelligence showing I. Q.'s above 110, the majority made a satis-

factory social adjustment; albeit, those with I. Q.'s in the dull normal group (75 to 89) did almost as well as the total in the conduct disorder group.

Psychoneuroses.

Anxiety states, panics, phobias, conversion phenomena, obsessive thinking, compulsive behavior, tics of various sorts, hypochondriacal and neurasthenic like complaints, in distinct psychoneurotic constellations or patterns. The end results, as judged by present social adjustment and freedom from neurotic symptomatology, were better in this group than in any other; 15 out of 21 were socially adjusted and free from symptoms at the time of the follow-up interview.

Since the situational reaction group, comprising conduct disorders, personality problems and psychoneuroses, is that group of problem children who would be expected to respond most favorably to treatment, we made an attempt to find some correlation between satisfactory social adjustment or unsatisfactory social adjustment and other factors in the case history. We approached this question from various angles; age on admission, duration of hospital residence, elapsed time between discharge from hospital and follow-up contact, intelligence, home conditions, and direct psychotherapy. The number of cases in any one grouping was not sufficiently large to warrant any conclusive statement, and in addition, there were so many intangibles in the treatment situation itself that we feel it inadvisable to draw any positive conclusions as to the reason for the kind of social adjustment made by the various patients. We do find a suggestion, however, that those children with superior intelligence (I. Q. 110 plus), those in the preadolescent years (10 to 13), those who showed a definite and marked response during the first six months of treatment, and those whose parents had faulty attitudes rather than psychoses or psychoneuroses, have a definitely better prognosis.

THE SCHIZOPHRENIC REACTION GROUP.

There were 14 cases in this group. These patients presented characteristic symptoms of dementia præcox. A diagnosis of encephalitis was excluded in each instance. The life history was negative for retarded mental development during the period of

infancy or the early pre-school period. Symptoms such as acute apprehensive states, confused or incoherent talk, mutism, negativism, hypersuggestibility, phobias, regressive habits or behavior, withdrawal of interest, suspiciousness, stereotyped behavior, obsessive compulsive phenomena, attitudinizing, neologisms, etc., appeared at varying ages, from the third year on. Four of these patients showed some improvement at the time of discharge from the hospital but these as well as the others, except one, have undergone further deterioration since. Only one patient, of the entire group of 14, is making a satisfactory social adjustment in that he is attending school, is up to grade, is a satisfactory member of the family group and is making a passive kind of adjustment with the children at school and in the neighborhood.

Schizophrenia occurs so infrequently in young children that it may be of interest to give a brief clinical sketch of each of these patients.

S. K. Onset at age of three years, with apprehensiveness, resistiveness and excited, productive, incoherent talk. When admitted at the age of four, patient soiled and wet himself, was mute, resistive and cataleptic. There was also attitudinizing and stereotyped repetitious movements of hands and arms. His reaction was detached and indifferent, with episodes of unprovoked acute anxiety and rage. At the age of eight, he is in a state school and is apathetic, indifferent, constantly masturbating and mute.

S. A. Onset at about three and a half years, with apprehensiveness, screaming attacks and a rapidly ensuing mutism. Admitted at the age of five years, with frequent unprovoked attacks of rage in which patient would strike his face and vomit. He was generally apprehensive and later showed complete indifference apathy, and jargon speech or mutism. He was likewise resistive, negativistic and seclusive, displaying stereotyped movements. At the age of seven, his condition remains unchanged. He is at home but the parents feel that they will soon have to seek institutional care for him.

M. E. Onset indefinite. At about the age of five years patient became gradually indifferent, irritable, with outbursts of silly laughter, gradually becoming less productive in talk. On admission at six and a half years, there was wetting and soiling and open masturbation, he fondled the nurses' breasts at every opportunity and was disinterested, indifferent, seclusive and neologistic. Echolalia, attitudinizing and stereotyped movements were also manifested. At the age of nine, he is in an institution and unchanged in his condition.

J. M. Onset at the age of three with excitement, apprehension, belligerent rages, incoherent speech and mutism. On admission at the age of six, was mute, seclusive, negativistic, inattentive, indifferent. Also, there were fits of

rage and open masturbation, stereotyped movements, attitudinizing and compulsive behavior. At 10 years of age, patient is in an institution, indifferent to his surroundings although seeming aware of them. He cooperates in a passive, automatic way.

R. L. Onset at three and one-half years, with masochistic rages, sleeplessness, wetting and soiling and rapidly developing mutism. On admission at age of seven patient was excitable, cruel and bit self and others in impulsive rages, she smeared faces and masturbated openly; likewise, she showed mutism interspersed with echolalia and was emotionally detached, seclusive, negativistic and extremely resistive. At the age of nine, she is hospitalized in a psychiatric hospital and although amenable and no longer excited, is fundamentally unimproved.

T. R. Onset at five years, with purposeless wandering away from home, fanciful disconnected stories, rages and irritability. On admission at age of nine, patient had frequent belligerent rages, wet and soiled himself and was incoherent in speech. Also, he was emotionally detached and at times apprehensive and seclusive. At the age of 11, he is living at home, goes to a small private school but is making no progress, is completely asocial, afraid of other children and emotionally inadequate.

M. S. At age of four, patient began to be indifferent to commands, inattentive, had temper tantrums and was silly in his talk. On admission, at nine years of age, he was resistive and overactive in a detached purposeless manner, disinterested, indifferent, seclusive and rather fearful generally. There was also inappropriate laughter and patient displayed a compulsion to poke his finger into the eyes of others. At the age of 11, he is living at home, is obedient and even tempered, and cleanly in his toilet habits. Patient is less timid but does not show any interest in playing with other children. There is still a good deal of inappropriate silly laughter and he is regarded as "queer" or "odd" by other children.

J. S. Onset gradual at age of nine, with gradually increasing retraction of interests, irritability, and preoccupation. On admission at the age of 10, patient was restless in a purposeless detached way, had occasional rages and was generally indifferent and preoccupied. He was, in addition, seclusive, wet and soiled himself, grimaced a good deal and reacted to auditory and visual hallucinations. At the age of 16, he is living at home and is a sophomore in high school. He is well behaved, cleanly, and although he has no interests in common with his associates, he appears well adjusted and free from psychotic symptomatology.

R. S. Onset at six years with anxiety, fears, doubts, and periods of excitability. Admitted at the age of 10, with facial tics, misophobia, hand washing compulsion and complaint of buzzing noise in head. He was preoccupied, tense, confused, incoherent at times and seclusive. Inappropriate laughter was likewise manifested and patient's attitude was one of questioning doubt. At age of 13, his condition is essentially unchanged and he is in a state psychiatric hospital.

D. W. Onset at age of seven, with rebelliousness at school, senseless stealing, rages, and disobedience at home. On admission, at the age of 11, he was excitable, irritable and told fantastic stories with homosexual content. Besides, patient had fits of crying, fears of the dark, was suspicious and complained of being "picked on and disliked" by other children. At the age of 15, he is in a state psychiatric hospital and has a well developed paranoid trend, relating to his being "framed" and spied upon. He complains, too, respecting secret dictaphones.

H. H. Onset acute at the age of 10½, with excitement, anxiety and fears. On admission, at the age of 11, patient was excitable, confused, overtalkative in an incoherent rambling manner, fearful, and had many delusions relating to somatic disintegration. In addition, auditory and visual hallucinations were present. At the age of 16, he is in an advanced hebephrenic condition in a psychiatric institution.

D. A. Onset acute at the age of 10, with excitement, apprehensiveness, and belligerent rages. On admission at age of 11, there was wetting and soiling and much oral sadism. Patient was preoccupied, indifferent and made impulsive assaults, also, he was seclusive, grimaced, and manifested delusions of a grandiose nature and ideas of somatic disintegration. At 16, he is in an advanced state of deterioration in a mental hospital.

B. N. Onset at age of eight, with an acute confusional excitement, characterized by apprehensiveness. Admitted at age of 12, patient was confused, perplexed, detached, seclusive and incoherent in speech, with much blocking. There was also fear of death and visual and auditory hallucinosis. This patient, at the age of 17, is living at home and in a moderately deteriorated hebephrenic state.

S. G. Onset at the age of 11, with belligerent rages against his mother and states of apprehensiveness. On admission at age of 12, he was irritable, seclusive, fearful, suspicious, excessively neat and had persecutory notions directed toward his mother. At the age of 15, he is living at home, extremely negativistic, refuses to eat with the family, is abusive toward his mother, and makes no social contacts.

SUMMARY.

Social adjustment.	Idiopathic epilepsy.	Mental deficiency.	Juvenile paresis.	Secondary behavior problems.	Personality and habit problems.	Conduct disorder.	Psychoneuroses.	Schizophrenia.	Total.
Satisfactory	3	5	0	2	14	26	15	1	66
Unsatisfactory	6	22*	7	19†	11	25‡	6	13	109§
Total	9	27	7	21	25	51	21	14	175

* 2 dead. † 1 dead. ‡ 1 dead. § 4 dead.

To recapitulate, this is a report of the outcome of 175 problem children whose maladjustment in the majority of instances was so severe that it necessitated hospitalization. No case included in this report had been out of the hospital for less than one year; well over half of the patients had been out three years or more. So far as the treatment accorded is concerned, it may be said that it was widely conceived and was both extensive and intensive except for those 64 cases belonging to the organic reaction group. There were 64 cases in the organic reaction group; ten of these were making a satisfactory social adjustment at the time of the follow-up contact. We wish to state, however, that for administrative reasons, we found it inadvisable to attempt a long term treatment of these cases. More adequate treatment might have resulted in a larger number of social recoveries.

The results in the situational reaction group (conduct disorders, personality and habit problems and psychoneuroses) were gratifying, as 55 out of a total of 97 were making a good social adjustment when the follow-up contact was made. The percentage of children making a satisfactory social adjustment was definitely higher in the psychoneurotic group. It is our impression that children who have superior intelligence, who are in the prepubertal years (10 to 13), who show a definite response to treatment during the first six months, and whose parents, although having faulty attitudes, are free from well defined neurosis or psychosis, have the better prognosis.

The outcome of the schizophrenic reaction group is exceedingly poor; only 1 out of 14 has made an at all satisfactory readjustment; the remainder became progressively worse. This certainly emphasizes the constitutional inadequacy factor, whatever it may be, in those cases which we call schizophrenia in children.

PROBLEM CHILDREN GROWING UP.*

By LEO KANNER, M. D., Baltimore, Md.

Studies of the development of ergasic disorders of adults have led psychiatric interest to a consideration of early personality formation. Studies of the behavior difficulties of children have raised the question of their significance as indications of future adjustment tendencies. Thus there is one arrow pointing backward from adulthood problems to their origins and evolutions, and another arrow pointing forward from childhood problems to their life-shaping potentialities. Reconstruction of devious careers has rightly become an integral part of psychiatric anamnesis, but the path of the second arrow has rarely been followed through from childhood to adulthood. Child guidance clinics, school adjustment centers and juvenile courts are usually compelled by the pressure of ever new demands to drop their relationships with older patients in the face of improvement, lack of coöperation, change of residence, referral to a social agency, institutional placement, graduation from school, termination of the court probation period or, quite often, a gradual and spontaneous loosening of mutual contacts.

During the last few years, attempts have been made to follow the destinies of individuals from the pivotal events revolving around early personality difficulties. In 1930, Sheldon and Eleanor Glueck [3] published their challenging account of the careers of 500 boys discharged from a reformatory. In 1933, Fairbank [2] reinvestigated 212 persons, 17 years after they had been studied at school age by Campbell as part of a district survey program. In 1935, Thom and Winslow [9] presented the results of a follow-up study of 50 problem children who had been given a poor prognosis, and 50 who had been given a good prognosis, finding in asocial tendencies a criterion by which future difficulties of all-round adjustment may be anticipated. Berk, Lane and Tandy [1] observed

* Read, as part of a symposium on Child Psychiatry, at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

the progress of 30 children who had manifested delinquency problems before the age of 10 years. In 1936, Hubbard and Adams [5] dealt with the factors affecting the outcome of child guidance clinic therapy of 100 children, considering the situation both at the time of referral and as it developed under treatment by the clinic.

In 1934, a follow-up program intended to cover the course of childhood, adolescence and early maturity was launched at the Harriet Lane Home, the pediatric department of the Johns Hopkins Hospital, where psychiatric service had been begun in 1930, in close connection with the Henry Phipps Psychiatric Clinic. The ages between a few months and 14 years at the time of the first examination were represented, and attention was given to every complaint for which a child was referred. The case material therefore includes cerebrogenic, endocrinogenic and toxic conditions, problems of sick and convalescent children, adjustments of the neurologically and orthopedically handicapped, innate personality disorders, reactions to situational stress, and the so-called everyday problems of the everyday child. An effort was made from the start to record the essential biographic, physical, intellectual, emotional, conative, environmental and constitutional factors in each case.

Between four and six years after a patient's first clinic visit, Miss Polly Bouck, a psychiatric social worker especially engaged for this purpose, made a study of the situation as it then prevailed. Data were obtained about the family's contacts with relief and other agencies whose records often threw much light on economic conditions, work habits, social attitudes and living standards. Interviews with school teachers brought information about progress in the child's studies, behavior in the classroom, regularity of attendance and type of parental coöperation. A visit to the home gave additional knowledge of stability of residence, neighborhood features, domestic routine, the family members' attitudes towards each other, the patient and the clinic, and any improvements or new difficulties that may have developed. Reëxamination at the clinic covered the child's state of health, scholastic abilities and interests, recreational activities, feelings towards family, teachers and playmates, ambitions, moods and habits, manner of getting along with people and, of course, the cessation, improvement, con-

tinuance or aggravation of the problems originally complained of. Attention was paid to the degree to which the child, the family, the school and the social agencies had been willing or able to carry out the clinic's recommendations, which themselves came in for a test of their soundness and applicability. Whenever indicated another intelligence test was given, a new physical examination was arranged or plans were made for renewed treatment of the old disorder or of problems that had arisen in the meantime.

Two hundred and thirty cases have thus been investigated or are now under investigation. The first 75 patients about whom reasonably complete information exists form the basis for this report. This group consists of 43 boys and 32 girls, 70 white and 5 colored children. There were six pairs of siblings and one pair of first cousins among them.

The age distributions at the time of the first consultation (between November, 1930, and February, 1931) and at the time of the follow-up were as follows:

Age at first consultation.		Age at reinvestigation.	
Age in years.	No.	Age in years.	No.
1	1	5	1
2	4	6	4
3	6	7	6
4	7	8	5

13	6	17	7
14	1	18	1

This group differs in its composition markedly from groups of equal size that come before the average child guidance clinic and those studied at our own clinic at later periods. When consultation service was first introduced at the Harriet Lane Home, the pediatricians began by seeking advice regarding obvious and striking maladjustments before referring children with milder and

the progress of 30 children who had manifested delinquency problems before the age of 10 years. In 1936, Hubbard and Adams [5] dealt with the factors affecting the outcome of child guidance clinic therapy of 100 children, considering the situation both at the time of referral and as it developed under treatment by the clinic.

In 1934, a follow-up program intended to cover the course of childhood, adolescence and early maturity was launched at the Harriet Lane Home, the pediatric department of the Johns Hopkins Hospital, where psychiatric service had been begun in 1930, in close connection with the Henry Phipps Psychiatric Clinic. This group differs in its composition markedly from groups of equal size that come before the average child guidance clinic and those studied at our own clinic at later periods. When consultation service was first introduced at the Harriet Lane Home, the pediatricians began by seeking advice regarding obvious and striking maladjustments before referring children with milder and

subtler difficulties. Hence major disorders figure more prominently in the cases under consideration. Whereas, for example, idiocy is represented in only 0.63 per cent of our total of 2400 patients, there are not less than 6.7 per cent idiotic children among the 75 reported in this study.

This report is not a final product but rather the result of temporary taking of stock, a resting point on the road to further observation of these children in the years to come. Its purpose is to show how they have progressed, what they have done and what has happened to them. No attempt is made to evaluate developments in terms of "cure" and "failure." Where the issue was centered around sweeping maladjustment, curiosity is directed towards the present state of the child's adaptation to his environment and the environment's adaptation to the child. Where the issue hinged on more specific disorders, attention is paid to these "symptoms," plus the factors determining the place now occupied by the patient in the general scheme of things. It would be much easier to state merely that so many enuretics now do or do not wet their beds or that so many breathholders now do or do not hold their breaths. Yet though the cessation of enuresis and breath-holding spells is doubtless a part of the therapeutic aim, the complaint is also a means of introducing a child, a situation and varying needs for corrections of bodily conditions, attitudes, parental management, grade placements at school and modes of interpersonal relationship. Complaints, such as of mild tics or nightmares, are sometimes associated with difficulties of a magnitude compared to which consideration of the symptoms itself must take second place. Hence our follow-up puts no less emphasis on the child and the situation than on the complaint that has served to introduce them.

In 26 of the 75 cases, feeblemindedness formed the nucleus of the difficulty. Under ideal circumstances, institutional placement would have been recommended for most of them. In the years of the depression, such facilities have been greatly reduced, so that only the most pathetic victims of dependency and neglect had any chance of admission.

Of 10 idiots and imbeciles, William B. is in a private institution; Morton F. was placed in the State Training School in 1931, re-

moved from there against advice and returned in 1935 when he became a menace to his baby brother; Irene L., committed with much difficulty, was stolen from the School by her mother, returned by the police, granted a few days' vacation to a relative who never brought her back; Julia K., Pauline B. and Antoinette L. are badly managed by feebleminded parents who would not consent to their placement; George N., convulsive, blind and hemophilic, is at home because a long waiting list has so far kept him out of the Training School; Gilbert K., a placid Mongolian, and Mary S., a good-natured cretin, are well supervised at home; Leo W. is not as yet considered abnormal by his deficient parents and his parochial school teachers.

Of 16 morons, eight had been referred because of poor progress at school. In the other cases, the main concern was reported as (1) restlessness and bad temper; (2) food capriciousness, temper tantrums, stealing; (3) hydrocele, the correction of which was expected by the mother to bring about improvement of vision and intelligence; (4) baby talk and stuttering; (5) enuresis, restlessness, sensitiveness; (6) indistinct speech and spoiled child reaction; (7) masturbation with fear that the child would "lose his mind"; (8) anxiety attacks.

Six of the children were placed in special classes for retarded pupils, two remained in parochial schools where they are doing poorly, four continued in rural schools which have no special classes, one went to a hearing conservation class, one to a school for blind children, and one was carried with poor success in a regular grade of a city school. Two girls left school at the age of 16 years; one is a well-behaved cretin who helps her mother with the housework, the other a city girl who manages to mask her retardation under an attractive exterior and is looking for a simple type of job. Application for admission to the State Training School was made for one child but he has not yet been accepted there.

As for "symptoms," all six instances of enuresis, two each of temper tantrums and restlessness, and one each of breathholding spells, masturbation, encopresis, sleepwalking and anxiety attacks were no longer present after four years, while temper tantrums and speech disorders persisted in three cases, restlessness in two, and food fussiness and stealing in one case each. Nine of the children are moderately well adjusted.

Of the others, Thomas F. has the double handicap of feeble-mindedness and blindness; Emily K. is deaf and has developed hypochondriacal trends; Elmore H. is troublesome at school and often plays truant; Albert H. indulges in petty stealing; John S. is reported as being heedless of danger; Otto B. masturbates openly in the classroom and beats smaller children; Wilbert McC., now 17 years old, has fierce temper outbursts, has forced sex relations on his brother and attempted to choke his mother and a little girl; when his father, who refused to have him committed, deserted the family in 1936, his mother asked that Wilbert and another feeble-minded son be sent to the State Training School but never filed the application, so that Wilbert is still at large.

Of the remaining 45 children, 12 fell in the group of borderline intelligence, 17 were dull normal, 12 were normally intelligent and eight were of superior intelligence. The myth of the constancy of the I. Q. has been exploded by Hildreth,[4] Richards [8] and others. Even in our small group, the I. Q. dropped within a few years ten or more points in 7 cases, and rose ten or more points in five. One of the increases occurred in a thyroid-treated cretin, one after recovery from lead encephalopathy. In the others, relations between the I. Q. changes and specific responsible factors could not be established with any degree of certainty.

Thus not even the I. Q. affords prognostic security, which is further influenced by unpredictable contingencies. Morton L. was rid of his tics and night terrors when he succumbed to meningococcus meningitis in 1936. Sidney K. had overcome compulsive habits when sarcoma required leg amputation in 1936, with death now imminent. The family pattern was altered noticeably by death of one parent in five cases, of both parents in one; serious illness of the mother in two; parental separations in 11 and reconciliations in four; the mother's remarriage in one; the arrival of new siblings in nine; change of residence in three; economic changes for the better in three, for the worse in 12, fluctuations in five cases. Four patients incurred accidental injuries, two resulting in cerebral concussions. Three underwent appendectomies and one a mastoid operation. Three each had pneumonia and bronchitis during the interval, four had measles, two had chicken-pox, one each had scarlet fever, pertussis, dysentery and gonorrhea, and one spent a few months in a tuberculosis sanatorium.

The difficulties of the children with I. Q.'s above 70 consisted mainly of reactions to illness in four (congenital malformation of the heart, celiac disease, lead poisoning, epilepsy), parental spoiling and oversolicitude in 18, maternal rejection in two, strain and stress at home in 10, at school in eight, and both at home and school in six. Sixteen of 47 patients are now doing well in every respect; 21 have made fair adjustments and give no cause for serious concern; 10 are poorly adjusted and require intensive psychiatric and social work which, in 5 cases, is carried on in collaboration with the juvenile court. Apprehension is justified regarding three boys and one girl whose delinquent acts and anti-communal attitudes have taken a turn for the worse. One colored boy has landed in a reform school. The school situation, comprising comfort, conduct, attendance and achievement in grades adapted to the pupil's abilities, is satisfactory in 17 cases, fair in 12, and unsatisfactory in 10. Of eight pupils who left school at 16 years of age, one is employed as telephone operator, two in domestic service, one helps at home, two are unemployed, and two are unemployable because of their personality difficulties. Parental cooperation was excellent in the work with 13 children, fair in 20 cases, and poor in 14. As regards the original complaints, hypochondriacal trends and invalid reactions yielded most readily to therapy. All nine patients so affected, as well as their families, could be made to acquire healthier attitudes towards health. All three instances of tics, two of pica and one of encopresis have cleared up completely under treatment. Enuresis was no longer present in 9 of 14 children, food capriciousness with or without vomiting in 8 of 13, temper tantrums in five of six, marked restlessness in one of three, speech difficulties in two of four, and truancy and stealing each in three of four children.

As one might expect, the best responses to treatment were obtained from the combination of stable and intelligent children, sound ancestry, tolerable home conditions and good family, school and communal coöperation and facilities. The more of these features were absent, the less gratifying are the results. Yet sometimes much could be done for a child even though parental understanding and coöperation were lacking and the general environmental conditions did not change appreciably.

George H., Alfred B. and Alvin C. are examples of these three categories: George, nine years old, healthy, I. Q. 118, had dramatic attacks of shortness of breath as reaction to false asthma alarm in connection with bronchitis, maternal oversolicitude, insufficient recreational outlets and sudden loss of friends due to change of residences and schools. Removal of the child's and family's scare, supply of play possibilities, visits to his former playmates and good coöperation did away with the trouble within a short time and made for good general adjustment. Alfred, 12 years old, undernourished, I. Q. 76, restless, given to temper tantrums, enuretic, a masturbator, doing poorly at school, grew up amidst violent fighting between an alcoholic, tyrannical father and an hypochondriacal mother who neglected her children; several relatives were psychotic and he himself had had infantile convulsions. Nothing could be done to change the horrible home situation or to board Alfred, who at 18 still has the same difficulties and failed in several places of employment provided for him with the help of the clinic. Alvin, 10 years old, healthy, very childish, restless, mischievous, not progressing at school despite an I. Q. of 134, playing truant, stealing, lying, staying out late, blinking his eyes and shrugging his shoulders, comes of a home kept in constant uproar by his matrimonially disappointed, chronically excited, forever agitated mother, whose spineless husband has and claims no voice in domestic affairs. Alvin, followed closely for several years, has learned to emancipate himself from his mother's domination, conform to reasonable rules and conventions and balance his work and play habits and has rid himself of his earlier difficulties, of which blinking is the only residue. Though the home conditions remain the same, he is now quite well adjusted, has matured considerably, does satisfactorily at school and has developed a nice sense of humor and tolerance.

SUMMARY.

A brief résumé of a follow-up study of 75 problem children is presented after the first interval of between four and six years. The present mode of adjustment is reviewed in its relations to health, intelligence, home and school conditions, family coöperation, the rôle of unpredictable contingencies and the complaints with

which the patients had been first brought to the clinic. The need for brevity has precluded detailed accounts of individual cases which, however, are drawn on succinctly to serve as illustrations. There is hope for continuation of the follow-up of these and other patients for at least the coming decade. Studies of this nature may help to throw light on prognostic expectations, furnish empirical data about actual developments and their determinants, intrench respect for relativistic pluralism in the investigation of human behavior and show the way to the improvement of existing imperfections of psychiatric therapy and communal resources in dealing with problem children.

DISCUSSION ON CHILD PSYCHIATRY.

Dr. James K. Everhart (Pittsburgh, Pa.).—Mr. President, we have witnessed in recent years an ever-increasing invasion of the field of psychotherapy by lay analysts, psychologists with a smattering of analytic knowledge, certain others who have taken a course in analysis, and various other persons poorly equipped and untrained, yet confident that they are qualified for the serious and difficult task of attempting to treat sick persons by analytic methods.

Mental healing is without doubt one of the oldest therapeutic measures used by mankind. What is of vastly more importance is the fact that mental healing is gradually being divested of its supernatural and mysterious aspects; its basic truths and principles are being unfolded, with the result that psychotherapy is being brought more and more into the domain of scientific medicine.

It is difficult for some of us to separate the physical from the mental. It is not yet universally understood how emotional disturbances affect functional and organic processes. Psychiatrists have long recognized this but it would seem that the need is for more frequent recognition of psychiatric problems by all medical men. Our progress has been for so long a time along the obvious lines that mental and emotional problems of life have been neglected or overlooked.

Certainly the pediatrician needs the psychiatrist and if psychiatrists would only speak in simpler terms and talk to us in easily understandable language, I have no doubt it would help us greatly in practical application of some pediatric principles.

However, I have neither the desire nor the qualifications to discuss controversial issues. My interest in the subject is solely as it can be applied to the practical, every-day problems of those who are dealing with children, whether it be the pediatrician or the so-called general medical practitioner. The physician who deals with the child should consider the child as a whole—his mental as well as his physical side.

In 1889, the beloved Dr. Jacobi said, in the first presidential address delivered before the American Pediatrics Society, these words:

"Unless the education and training of the youth is carried on according to the principles of a sound and scientific physical and mental hygiene, neither the aims of our political institutions will ever be reached nor the United States fulfill its true manifest destiny—of raising the standard of physical and mental health to possible perfection."

The pediatrician who would share in the noble aspiration of Jacobi must be a teacher and adviser. This function devolves not alone upon the pediatric instructor in colleges and hospitals and in public and child welfare agencies, but decidedly on the practicing pediatrician, the family adviser, in all questions concerning the well being of children.

In dealing with problems of childhood, parents definitely enter the picture. Unquestionably, many problems are imposed upon the child by his parents. The family is, of course, the most powerful force in the emotional development of the child, but the family is still an imperfect institution. A majority of families are, after all, charged with undercurrents of jealousy, resentment, and all sorts of feelings not conducive to the healthy development of the child. Parents are so preoccupied with the child's physical and intellectual development that they forget emotional development. This may be accounted for on the basis that the child's physical and intellectual problems can be recognized as separate from the parents' own physical and intellectual problems, whereas the child's emotional problems are part and parcel of the parents' own emotional problems. This means a loss of objectivity. Many parents are often unable to give the child the sort of emotional guidance that is needed.

Parents frequently are unable or unwilling to recognize this. Thus we have not only the child but also parents to deal with, and as we all know, the latter often are more difficult than the child himself. A large part in the successful handling of these cases lies in our ability to give parents a better understanding.

Our experiences and observations have convinced us that behavior difficulties are never trivial. Ill-temper, habit of failure, jealousy, rage, overdiscouragement, marked fluctuations of energy, moodiness, evasion of tasks and hard situations, "nervousness," oversensitivity, and petty delinquencies of children are danger signals which indicate that something is amiss in the interplay of the individual and his environment. It is difficult to work back to the source or beginning of many of these troubles. Recognition of etiologic factors is difficult. At this point the pediatrician is definitely and directly involved, for early recognition offers the best opportunity for correction. Parents should be reached because of their direct responsibility. They should know that the early emotional set-up is vital.

The pediatrician in private practice meets the more intelligent class of parents; those who eugenically offer the best hope for the physical and mental progress of mankind, and also parents who are best equipped to accelerate propaganda for child betterment. As an educator, his opportunities are exceptional. The scope of his teaching should extend beyond the physical attributes of his patients to include their mental and emotional natures—their total functioning. He must instruct parents in physical and mental hygiene, but he should also impress upon them the importance, to their children and to children generally, of early character building, of laying the habit and behavior foundations early in the life of the child.

Intelligent parents feel the need of a better understanding in the mental guidance of their children, but unless their physicians volunteer aid, they may seek help from non-medical sources, assuming rightly perhaps, in some instances, that their medical advisers are uninterested, too busy or incapable. Some of the agencies to whom parents appeal are capable of giving helpful service relative to the particular behavioristic abnormalities of which the elders complain, but often they do not offer all-embracing counsel. Only in

certain instances is the advice based on thorough studies of the child's physical, mental and emotional history, and of his present mental and emotional environment and training. Frequently, the child as a unit is not thoroughly appraised, and the advice often reflects the bias or the habit thought of the individual consulted and relates only to one symptom or group of symptoms.

Certain specific and constitutional diseases are decreasing, but mental aberrations are not. One might almost ask why this is so. A plausible answer is not possible here; but certainly the loss of moral and spiritual values in the home, so evident in recent years, must carry a part of the responsibility. We attempt eradication of smallpox, diphtheria and typhoid on a large scale by preventive measures. Can many of our psychiatric problems be curbed similarly? Early detection of factors that lead to mental ill health might check the ravage. Do pediatricians and other physicians pass the responsibility to others when the mantle fits perfectly on their own shoulders? Are there so few understanding parents because there are so few understanding physicians?

My plea is to urge that physicians become more conversant with the education, social, psychologic and especially psychiatric phases of child health, so that they may become worthy preceptors and consultants in the homes—family advisers for children—and that they may remain leaders in all activities directed toward the promotion of child welfare.

PRESIDENT CAMPBELL.—Since Dr. Meyer came to America and took up his work in the Middle West, he has shown continued interest in the problems of childhood, from that date until his initiation and support of this liaison work of which Dr. Kanner has brought us out a mature development. Dr. Meyer!

DR. ADOLF MEYER (Baltimore, Md.).—Considering the hour and also what we have heard this afternoon, I am not altogether certain where it would be wisest to put the emphasis. On the one hand, we have the accounts of earnest workers, some of whom I know well, and others I should like to know more of than is possible with the limited data offered in a crowded symposium. I have been particularly interested, however, in the words that we have heard last. It seems to me that it is a great misfortune that most of our colleagues who are not psychiatrists feel an obligation to make excuses for the distance that exists between us and between those who are doing particular work along the lines that the pediatrician outlined so well. Why is it? I suppose, as in every field, it is essential that the actual worker focus on the type of material that actually presents itself and which he considers inviting and perhaps difficult, but intriguing enough to devote himself to. Another avenue, of course, is that of first acquiring one or another form of methodology difficult to follow, unless one has the opportunity.

Some of us from the beginning, others later, and others, in spite of having gone through somewhat devious routes, have learned to recognize certain principles which I think every practitioner will be able to understand and which will also mean a good deal to those trained in particular methods. We

have learned definitely to value the concrete data with which we have to operate, including, of course, with the child also the situation. We are willing to develop the propinquity to the facts as they are and to see the situations.

Of course, when you hear Dr. Allen speaking of his particular rôle in connection with work, you have to take into consideration that he describes his particular share in what belongs, after all, to a full fledged organization.

When we hear the more definitely analytical and technically prepared person, we also have to reckon with the fact of the parents not being particularly drawn into the situation, in order not to spoil the analytic rapport, not betraying the child and troubling the parents with charges and criticisms levelled at them—those are points which the analyst wants to avoid in order to have his own field as little as possible contaminated by the factors which he would rather leave to the incentive or sensible attitude of the parents who immediately take a more hopeful and less interfering attitude, one of hoping that things that they misunderstood before will get better by developing a relationship that is adapted as much to the requirements of the analyst as they are to the child.

So I think there are inevitably, with either of the various types of analytic or other so-called approaches, irrespective of the particular kind a good many of those things in common that Dr. Everhart described and that the pediatricians stand by and what we might call the attitude of common sense, of progressive, interested, resourceful common sense.

The effect this symposium has had on me is this, that I find myself confronted with exceedingly interesting data and material, on the whole, on the intermediate ground between the very specialistic preoccupation and technic and accounts. These very often are given without any time statement. It is rather difficult to get from the account that tremendous importance of time and what must fill the intervals between what is mentioned in the clinical or therapeutic records. One misses, even in the very specialized accounts, the reference to points that I described a moment ago as those that come quite naturally and incidentally.

Evidently there are in the selection of methods, as in the selection of patients, in the selection of physicians, in the selection of hospitals, factors which tend towards those people being brought together that have a certain similar expectation and also similar items in which they find means of actual cooperation.

The summary accounts that I heard in the last few papers leave me somewhat baffled, because it is impossible to get in that sort of summary a feeling that one knows enough about the matter. One gets the feeling of too much hopefulness or disturbance of the hopefulness.

Nevertheless, if we could focus our discussions on material in which various participants have had a share, we might gain a great advantage. I remember, in 1916, the program of the American Association for Psychopathology made it a point to discuss a small number of patients with whom the three reporters had all had responsible contact. It was out of that I think quite a few of us learned a great deal and carried off that sense of relativity

of importance which one misses a great deal where one has accounts of one chapter and another chapter, without that actual individual contact between workers with identical or similar situations.

I must say that my discussion of such a general character has only little value as compared to what a discussion by the members of the symposium of each other's contribution would have. I, therefore, would like to express the hope that those who have offered us presentations will with their specific perspectives fall in line now and tell us freely wherein they feel their contribution was helped or challenged, with free mutual criticism of the data that we have listened to. I am sure all of us were interested, or there would not be as large an audience present at this hour to hear the end of the discussion.

Dr. Erwin Wexberg (New Orleans, La.).—I want to give my wholehearted approval to the paper of Dr. Frederick Allen, and particularly so to his criticism of what he calls the historic approach.

The only thing which counts obviously is to find out what the individual is driving at. We need understanding of the pattern difficulty of the historical development in grown up people. But in children this pattern is just being developed, it has not so much of a past; it mostly has a present. So what we have to find out in a child is the present aims and attitude, and this is easier than in adults because we can find out more from direct observation. The misleading point of view is to apply the psychology of the neurosis of grown-up people to children and to consider children as though they were adults, as though they had definite patterns which have to be found out in order to understand the actual situation.

Therefore, I wouldn't agree with any point of view which would amount to the statement that there are psychoses or neuroses or criminality in children. We have plenty of neurotic, psychotic children, but their meaning is something entirely different from what they mean in adults. It is of exceeding importance for our work to keep this distinction in mind.

Dr. James L. McCartney (Catskill, N. Y.).—During the past ten years, several thousand children have gone through the clinics in New York City. Some of those children that go through the schools of New York City have got into the state prisons. I have had the opportunity in the past six years of seeing about 6000 boys under 17 years of age, of which number 72 per cent came from New York City. It is interesting to note that of those 4000, only 8 had been in child guidance clinics. That means something, I feel, because of all the other delinquents, none had been under psychiatric care previously.

An analysis of those eight cases is rather interesting: Two were definitely schizophrenics; three were epileptics; and three were postencephalitic cases, obviously hopeless to begin with, and there was little the clinics could have done for them. Yet the actual behavior cases did not arrive in the reformatories, possibly because they received treatment earlier. The question comes up, has the work in these clinics been evaluated in relation to the state hospitals?

DR. DAVID M. LEVY (New York, N. Y.).—I want to take up Dr. Meyer's and Dr. Campbell's challenge and tell what I think of the other papers, including my own.

I should say first that the feeling of dissatisfaction that Dr. Adolf Meyer had at the end of this symposium should be partly related to the Program Committee. A number of papers were assigned to some of us in this symposium with no definite notion of integrating the field in any way. We were asked to give the papers without relation necessarily to any other papers on the program. It so happened that the papers do, by coincidence probably, integrate themselves into a certain type of response that I think at least represents the mature thought of the field today.

I think the papers that were given this afternoon could not have been given ten years ago. I see in them all a fine development of the particular stress that they place in this field.

Of the papers given, one definitely showed a particular type of development in the psychoanalytic work in children, in which the method so brutally attacked by both Dr. Allen and Dr. Wexberg was especially effective and applicable to those particular cases. Dr. Allen's paper, on the other hand, stresses a method which no one has developed to as high a degree as himself, namely, as I see it, the particular values that the child gets in therapy from the living personal relationship with the therapist, with the possibility that from that relationship the child may acquire a set of values which he can utilize in his growing relationships with others.

Dr. Plant's paper represents a mature development of an emphasis which I remember his placing for at least the past ten or twelve years, namely, on those stresses that come upon the child through the social situation; and his paper properly gave apt illustrations of the therapeutic success in those cases in which this social stress is recognized and the relief of which by an entirely different method from that of Dr. Allen or from the psychoanalytic method, was of real therapeutic effect.

The last two papers were, I think, important because we do need follow-up studies, not only to keep books on our results but more importantly to study our therapy in terms of the effect on the child. Our follow-up studies have a special value in testing our therapeutic philosophy, hence I hope to see more and more of this type of investigation.

As for my own paper, it had nothing to do with therapy, nothing to do with follow-up. It was a contribution, if you wish, to psychodynamics essentially and attempted to show that the privation of certain emotional values in the life of a child may have a distinct effect on the pathology of the child to such a degree that we can't recognize actual psychopathology in the child.

I think Dr. Wexberg's optimism that there are no neurotic, psychotic and criminal children is a very happy optimism, but quite an illusion.

DR. MARGARET W. GERARD (Chicago, Ill.).—Dr. Levy has so beautifully summarized and evaluated the various papers that I have nothing to add to this. I would, in relation to my own paper, like to clear up a few points which

I feel perhaps were misunderstood. Dr. Meyer suggests that in child analysis, the parents are eliminated. I think perhaps that is because in the discussion of the analytic material in a very short time, one does not attempt to go into the total picture which covers over a year or longer and, therefore, only the outstanding factors are discussed. But the parents are always considered, and as far as confidences not being betrayed, these confidences very frequently are given to the parents by the children themselves later in the analysis, and the parents are helped during the process in the therapeutic angle in relation to the child.

As for the research element, which I think is most valuable in analysis because of the long-time therapy which is difficult, inasmuch as one can get only the child and his attitudes, the more we know of what is actually happening within that child and are not influenced by the parents' evaluation of them, the better.

In Dr. Wexberg's reference to the historical element in child analysis, I think he perhaps confuses what happens in child analysis. Our orientation is not to what did happen but what is happening, what is the problem of the child at the present moment, how he is solving it and what is the method for better adjustment. And if historical material enters in, it comes merely as secondary to the immediate problem and the reality situation.

Dr. Frederick H. Allen (Philadelphia, Pa.).—I felt very much as Dr. Levy did about the extent and diverse nature of the program. Possibly there was a little too much on it. The main value, I think, of meetings of this kind isn't the type of presentation, but the fact that we have been getting a free give and take discussion where we can iron out some possible differences on these important subjects. As the Program Committee did write and ask us to choose our own titles so they were not in relation to what each person was going to do, but the field itself has been of a type that made it possible for many of these papers to take a certain direction because in this field as it has developed in the last decade or two, more and more we have been interested not only in the theoretical aspects of this whole problem but in the ways in which these problems are actually lived out in action and how we who are interested in the problem of therapy can really make effective whatever point of view we are applying in effecting change in the child.

I think that this program has been interesting in that it has revealed different ways of approaching these problems. But as I see the different ways and hear the discussions of them, I am convinced that they all have value. There is no one way of doing them. It certainly is true that in the application of a point of view, in applying a therapeutic process, in finding one's self in it in a very real sense, it does require a good deal of integrity, a good deal of understanding and a good deal of conviction on the part of the individual applying it, so that it does come to life through what the therapist himself can put into it in the way of his own understanding and how he can thereby help the child to a little clearer appreciation of what he can be in the continuing realities of his own life.

I was particularly interested in the material Dr. Levy presented. He has made some real contributions in this study of maternal relations to the child. I couldn't help but think of some of my own cases as he was discussing the point of affect hunger, how difficult it is with children of that type to really get any kind of working contact with them, because of the tendency to hold themselves aloof, to protect themselves from ever getting into any relationship with anyone through putting any of their own feeling into it. There are two aspects of that type of problem that to me appear important, one is the actual deprivation that the child has had in his early experiences, but possibly the more important is the fact that the child coming out of that kind of an experience finds that he can neither take affection from others nor can he give it.

The thing I am most struck with in that type of child, is that he is unable to give any of his own feeling. It is hard for him to put any of himself into the relation in order that it really can become a growing experience to him. He has become used to protecting himself from any further deprivations, from any further trauma as a result of having difficulties with people, by just surrounding and encapsulating himself in this almost affectless way that Dr. Levy has described, and he therefore finds it hard to get anything out of the work of the therapist, because the latter is measured not so much by what the therapist puts into it, as by what he can stimulate the child to put into it of himself, to find what qualities are his and what he can really live with as a part of himself.

Dr. Leo Kanner (Baltimore, Md.).—There is just one thing I want to say. I have heard so much today the word "approach." I have heard of the psychoanalytic approach, Dr. Allen spoke of the approach, Dr. Wexburg mentioned the word approach, and I have been wondering to just what extent it goes, if it doesn't really show something more than a word, whether it doesn't have more connotation than just the use of the word. The thing that it implies is that we are here with something, with an armamentarium, with some tools ready to approach the patient who comes to us. I think that the word "approach" is justified all right, but perhaps with another, a different connotation, and that is we are *being* approached; we don't approach the patient. There is a patient and a situation that approach us. It is not only the parents who approach us; with every patient there come a child, a home situation, a community situation, with many aspects, some of which possibly are difficulties of the child and others which puzzle the parents, sometimes the teachers in school, some of which puzzle the juvenile court judge, and in my case many of them puzzle the pediatrician who sends the child. They are approaching us with problems of one or the other or problems of several of these groups, and we must deal with the facts that we see before us. In so doing we are entitled to take a breath every once in a while to see what we are dealing with and how these things group themselves, but I would suggest to myself (I always do) that in taking that breath one doesn't need to hyperventilate because of the possible results.

MENTAL CHANGES INCLUDING APHASIA IN A PATIENT WITH SICKLE CELL ANEMIA.

By BEULAH BOSSELMAN, M. D., and S. H. KRAINES, M. D.,
Psychiatric Institute, University of Illinois, College of Medicine.

The occurrence of mental symptoms or particularly of aphasia in a patient with sickle cell anemia has not, to our knowledge, been reported. Kampmeier [1] recently described repeated attacks of neurologic disturbance, including hemiplegia, in a patient with this disease, and refers to reports [2] of four other similar cases. Kampmeier's patient and one of the others had blood in the spinal fluid. Another patient showed postmortem evidence of subarachnoid hemorrhage with cerebral softening; necropsy of another revealed recent diapedesis of red cells into the meninges, a small area of cerebral softening and small petechiæ in some of the nerve trunks. Our investigation indicates that there is only one case on record at Cook County Hospital of pathologic changes in the central nervous system found postmortem in a patient with sickle cell anemia. These changes consisted of chronic leptomeningitis and occasional recent perivascular extravasation of blood in the basal ganglia. Steinberg [3] in 1930 reviewed all of the necropsy reports, a total of 16, of patients with sickle cell anemia. No pathologic changes in the nervous system were observed in any of these examinations.

Report of a Case.

W. C., a negro boy of 13, was admitted to the Research and Educational Hospital, November 5, 1936, because of mental symptoms. The boy had been

[3] Steinberg, B.: Sickle Cell Anemia. Arch. Path., 9: 876 (Apr.) 1930.

subject to recurrent attacks of weakness and tachycardia, sometimes associated with slight fever and with pericardial pain, since infancy. In 1929 he had first been seen at the Research and Educational Hospital where a diagnosis of sickle cell anemia was made. In 1930 a splenectomy was performed. Following the operation he was kept under observation by Dr. Poncher of the Pediatrics Department. The boy continued to have symptoms of weakness and tachycardia following exertion but otherwise got along well. He attended school half-days. School reports indicate that his grades were average during 1935-36, and poor during the fall of 1936. No speech disturbances were noticed. In October, 1936, the boy's mother observed that he omitted words when reading and did not seem to understand corrections. During the following week it was noticed that he mispronounced words, no longer observed his former routines and expressed no interest in them. He spoke in a loud voice, did not respond when addressed, and on occasions seemed not to recognize members of his family. On the hospital ward he at first was restless and made irrelevant responses when addressed. He was examined by us first on November 11, and subsequently on six occasions, the last examination being on May 11, 1937. He was given on each occasion a set of simple verbal questions and directions, as, "What is your name?" "Write your brother's name." His responses at first were only 18 per cent direct and relevant. Most of his irrelevant responses were in the form of stereotyped phrases, as, "Wendell" and "I want to see my father." Sometimes he said, "What?" and "Huh?" His written responses were not noticeably different in quality from the spoken responses. The same set of questions and directions were then written, and his responses from the first were 100 per cent correct (Table 1). Tests for identification of such familiar objects as comb, pen, envelope, revealed the fact that at first he could not name any of these objects, though he showed an ability to use them correctly. When the names of the objects were written, he picked them all out correctly. His ability to name objects gradually improved, so that by January, 1937, he named correctly 50 per cent of objects presented, and gave garbled names to the other 50 per cent. No further improvement has taken place since January. During the patient's stay on the ward he became less confused, gradually cooperated better in ward activities and showed increasing interest in those around him. The mother states that the boy shows persistent changes in personality, particularly increased irritability and restlessness, a preference for infantile games, and a tendency to make grandiose statements. The results of a Stanford-Binet test given in February, 1937, indicated an I. Q. of 50. A drawing made at the same time scored according to Goodenough indicated an I. Q. of 75.

Comment.

Weisenburg's [4] studies of aphasia indicate that in the great majority of patients with this symptom, there is a lesion involving the

dominant hemisphere of the brain. As this patient was right handed, it is probable that his left hemisphere is involved. The changes in personality resemble those described in known frontal lobe lesions, and the predominance of the auditory receptive defects suggests temporal lobe involvement. The only nervous system changes so far reported in this disease are those associated with hemorrhage, and the patient's symptoms suggest the likelihood of multiple petechial hemorrhages into the brain. The mechanism of such hemorrhages in sickle cell anemia is unknown, and the subject requires further study.

Summary.

The case is reported of a colored boy, aged 13, with sickle cell anemia who suddenly developed mental changes including aphasia. The occurrence of multiple small cerebral hemorrhages is suggested as the most likely cause of the symptoms.

Comment.

THE PROBLEM OF THE SEX OFFENDER.

There has been much public agitation of late owing to a series of sex offenses against children, often including murder, in metropolitan centres, raising the question whether such offenses are on the increase. Serious consideration is being given to legislative and other measures for dealing with this evil in which it is commonly accepted that psychiatry may have something worth while to say.

In order to take stock of the situation in a careful and dispassionate way the National Committee for Mental Hygiene at its twenty-eighth annual meeting at the Hotel Roosevelt, New York City, November 10, held a symposium on "The Challenge of Sex Offenders," to which contributed leaders in psychiatry and criminology.

Dr. Edward A. Strecker, professor of psychiatry at the University of Pennsylvania, presided over the symposium and opened the discussion with the statement that the press had overemphasized the present "wave" of sex crime. "It is doubtful," he said, "that there is an actual increase in the number of these sex offenses. Indeed, it seems likely that at certain times in history they were more prevalent. There is no place for sickly sentimentality in dealing with this problem, but the line of demarcation between normal and abnormal sexual manifestations is often quite faint and abnormal sexuality has its representation in miniature in normal sex life. It is the duty of the law to protect the public. It must continue to do that. But over and above this there should be an effort in the direction of better understanding. Prejudice and intolerance should not be permitted to becloud constructive judgment."

The Hon. Austin H. MacCormick, Commissioner of Correction of New York City, in describing "New York's Present Problem" also expressed the opinion that there has not been a serious increase in sex crimes. He stated however: "Frankly, I do not know whether sex offenses are on the increase or decrease in this city and I doubt that anyone does. It is my own opinion that there has

been very little change in either direction in the last few years, but there are no adequate statistics with which to prove or disprove that statement. Thousands of sex offenses of one sort or another are committed every year without ever coming to the attention of the police or getting into the statistical records. Victims of or witnesses to sex offenses are reluctant to report the matter or to testify if an arrest is made. For this reason, and also because so many complainants and witnesses are children whose evidence is unreliable and easy to controvert, the percentage of convictions in sex offenses is not high. In 1936 in New York City, 277 arrests for indecent exposure resulted in 150 convictions and in 66 persons being imprisoned or sent to a hospital for the insane. Four arrests for rape of children between the ages of 7 and 12 resulted in 2 convictions, 20 arrests for rape of children from 12 to 14 years of age resulted in only one conviction, and 772 cases of rape of girls between 14 and 18 years of age resulted in 183 convictions. One hundred and seventy-five arrests for sodomy resulted in 61 convictions and in 45 persons being imprisoned or sent to mental hospitals. Three hundred and thirty-eight arrests on the charge of impairing or endangering morals of children resulted in 145 convictions and in 89 persons being imprisoned or sent to hospitals."

Commissioner MacCormick stated that the ideal method of handling the problem would be to put all cases under observation in a hospital well-staffed with competent psychiatrists and to secure a psychiatric diagnosis, at least, before the case is settled in court. "We do this," he said, "in cases coming before the Court of General Sessions but the city lacks the facilities for doing it with all the cases which the Court of Special Sessions and the Magistrates' Courts must handle. It is certain that there is not room enough at Bellevue or in any other New York City hospital for all those who should go there and remain long enough to insure an adequate diagnosis."

In concluding, Commissioner MacCormick said: "Until the attitude of the people as a whole towards sex is more rational, until it can be discussed more frankly and more intelligently, until people realize more fully what damage repressions and complexes and maladjustments can do to a normal mind, and until we approach the problem with sustained intelligence rather than in bursts of occasional hysteria, we must expect sex offenses to constitute a major problem for society."

Dr. Karl M. Bowman, director of the psychiatric division, Bellevue Hospital, New York City, spoke on "Psychiatric Aspects of the Problem." He pointed out that one of the difficulties is to come to any fundamental agreement as to what constitutes normal sex behavior, citing instances of conflicting concepts in different cultures and even within our own culture. The practice of birth control offers an example of "a particular type of sex behavior which is considered abnormal and perverse by one group and normal and natural by another."

"Our cultural attitude toward sex is generally one of extreme repression," he continued, "and towards no other instinct or drive of the personality are such extreme repressions and control maintained. This being the case, we find that unstable persons very frequently have great difficulty in adjusting to the conventional demands of society concerning sex behavior. Every psychiatrist is familiar with the fact that in practically all neurotic individuals there exists a deep-rooted sexual problem. The other half of the story, however, is that in most normal persons there is a deep-rooted sexual problem, but that the individual is able to carry on in spite of this. We do not find that the neurotic necessarily has any greater sex problem than the normal individual. Often he is merely unable to adapt himself so well to the stresses and strains imposed by such a problem. While helping to solve his sex problem may help him to get into a more normal condition, it is not fair to attach the whole responsibility for the break-down to the sex problem."

Dr. Bowman stated that the feebleminded as a group are no more likely to commit sex offenses than persons of normal or superior intelligence. However, he added, society has accepted the idea of permanent segregation for feebleminded sex criminals but it still lacks any method of dealing adequately with those of normal or superior intelligence. He also stated that definite psychoses account for only a small group of sex crimes.

"We can mention specifically," he said, "personality changes following epidemic encephalitis, in which there is often increased sex drive and lack of inhibition; certain epileptic furors and confused states with violent sexual assaults; a general increase in sex drives with a lack of inhibition in manic excitements; certain bizarre and peculiar sex crimes in schizophrenia; and certain crude sex assaults in general paresis and other organic brain diseases."

He stated that the majority of revolting sex crimes are committed by persons who are not legally insane, and who could not have been committed to mental hospitals if they had been seen shortly before such crimes occurred.

" If we try to understand the causes of sexual maladjustments," Dr. Bowman said, " we find they depend on three things—the constitutional make-up of the individual, both physical and mental, the culture in which he lives, and special conditioning experiences which may produce special attitudes and sensitivities."

He closed by stating that no simple solution to the problem is to be expected. " Simply passing more laws or making penalties more severe will not solve the problem. The public is demanding some simple, easy formula for dealing with this problem. No such formula exists. The problem is exceedingly complicated. More study and research are needed. The methods of psychiatry offer the best opportunities of studying and acquiring further knowledge in this field."

Dr. Winfred Overholser of Washington, D. C., contributed the closing discussion in this symposium, his subject being " Legal and Administrative Problems in Dealing with Sex Offenders." He commented upon the public furors which accompany the socalled crime waves and deplored the demand for new and stringent laws which occurs periodically. " The enactment of laws relating to offenders is rather commonly conditioned emotionally," Dr. Overholser said, " rather than by a cold study of the needs of the situation, and when emotional excitement cools off laws which have been enacted under its pressure fall into disuse and become rusty. Another wave of excitement comes along and further cogs are added to the machinery, so that it is indeed small wonder that the whole jumble of gears fails to function efficiently."

Dr. Overholser stated that except perhaps in two jurisdictions in this country the right of the court to have mental examination made upon defendants is undoubted and in at least the larger cities the necessary personnel is available.

" It remains, therefore," he said, " in many cases for the judge to be impressed with the desirability of knowing something concerning the human material with which he is dealing. I speak particularly of sex offenders, although the same principles hold with regard to many other types of transgressors. The New York City Court of

General Sessions is perhaps the only court of general jurisdiction in the country which has before it a psychiatric report in all felony cases before disposition. Such a principle is unquestionably sound, and it is interesting to note that in 1929 the American Bar Association adopted resolutions advocating likewise a psychiatric examination before parole. In spite of the fact that this association of lawyers went on record in this progressive manner the procedure is still by far the exception rather than the rule.

" The desirability of a routine examination as against an examination only of defendants in whose cases the defence of insanity is pleaded, should not call for extended comment. . . . . The Briggs Law of Massachusetts embodies this principle of routine examination, providing for it before trial. This is ideally the time in which such examination should be made, since in no inconsiderable number of cases the expense of a trial has been saved by the recognition of mental disease in the defendant. Here is a law which has been in successful operation and which has over and over demonstrated its value for a period of 16 years; yet such is the tendency of the legal mind to shy at anything strange that when a similar provision was incorporated in a model testimony bill drafted by Dean Harno, of the University of Illinois, and submitted to the Commissioners on Uniform State Laws, it was omitted from the bill finally recommended by the Commissioners as being too revolutionary. This example illustrates the tremendous power of inertia which must be overcome if a more rational and scientific manner of dealing with offenders is to be brought into effect."

Dr. Overholser pointed out that another difficulty in dealing with the mentally pathological offender is that, although in a considerable number of cases psychiatrists would agree that a defendant is mentally abnormal, his abnormality is not of such a degree or kind as to be recognized by the law as calling for specialized treatment. The laws of the several states, he explained, are in general agreement in providing for the segregation in special institutions of those offenders denominated as " insane " and two states, namely, New York and Massachusetts, have special provisions for the truly indeterminate commitment of the so-called defective delinquent.

" However, no state in this country," he said, " and only one or two European countries, have special provisions relating to the

offender suffering from what is generally known as psychopathic personality. It is this group which constitutes a considerable proportion of the so-called sex offenders and which not unlikely makes up a fair percentage of the total criminal population. It seems safe to say that before the law can be expected to recognize this group as calling for specialized treatment it will be necessary for the psychiatrists to come to a better agreement on the delimitation of the group. The statistics which have been published by psychiatric clinics in courts and correctional institutions show such a wide discrepancy that it seems likely that the basal difficulty is in the criteria of diagnosis."

Dr. Overholser stated that in too many instances the so-called indeterminate sentence is such only in name and usually has a rather short upper limit in practice, so that while the public believes the offender will be confined for a long time he is often set at liberty within two or three years.

"Judges should be given even wider latitude than they now have," he said, "relative to the length of the period of confinement to be imposed and they should be governed to a considerable extent in their disposition by official psychiatric reports relative to the offender's mental state."

Parole boards, too, he said, instead of concerning themselves primarily with such statistical details as the proportion of sentence served, might do well if they paid more attention to the mental make-up of the convict whose parole is being considered.

It would hardly be expected that a colloquium such as this could reach any definite conclusions or formulate practical measures which might speedily be put into effect. The symposium served at least two purposes: it brought to light some of the popular misunderstandings relating to antisocial sex behavior; and it exposed the difficulties of dealing with such phenomena, owing partly to lack of agreement in definition and partly to actual lack of data concerning many aspects of the problem.

The significance of sex in both normal and abnormal mental states has been so much labored in recent years that it is hardly necessary to stress this fact. Notwithstanding the paramount rôle of the sex function in health and disease it remains true that in medical education it is altogether inadequately dealt with and too often neglected entirely. The result is that medical students become

practitioners of medicine with little knowledge in this field which goes beyond anatomical structure and tissue pathology.

Sex crimes such as readers of the daily papers are all too familiar with, and which will always have to be reckoned with, do bring home with emphasis the fact that organized investigation in this domain has been lacking and is still lacking. In large part it is probably the old story of avoidance of what has been traditionally regarded as unseemly and distasteful, if not unmentionable—an artifact of our one-sided culture.

Fundamental studies are needed in which biology, psychology and psychopathology, sociology and criminology must collaborate. A special division of a well appointed and well manned psychiatric clinic would probably be the place where such studies could best be carried on. In the study of the individual sex offender as in that of a psychotic patient the determination of suitable disposal usually offers no great difficulty; the difficulty resides in providing the means of doing the thing which should be done. It would be through the accumulation of data from continued studies such as herein contemplated that society might learn what measures may be best in dealing with sex offenders, what may become possible in the way of prevention and what enabling legislation may be required.

News and Notes.

GRADUATE COURSE IN PSYCHIATRIC NURSING.—The New York State Department of Mental Hygiene offers to qualified graduate nurses a course of eight months in psychiatric nursing at the New York State Psychiatric Institute and Hospital, New York City. Nurses who have had three or four months affiliation are given preference in enrolment. The class will be admitted February 1, 1938. Board and laundry service are provided during the course.

For further information address Dr. Nolan D. C. Lewis, director, New York State Psychiatric Institute and Hospital, 722 West 168th Street, New York City.

SOUTHERN PSYCHIATRIC ASSOCIATION.—The third annual meeting of the Southern Psychiatric Association was held in San Antonio, Texas, October 8 and 9, 1937, with more than two hundred and fifty physicians from all parts of the South in attendance.

The meeting, which was by far the most successful held yet by this organization, is a striking indication of the healthy growth of interest and activity in the field of psychiatry in the South. In addition to the several hundred physicians registered, many local physicians, social workers and nurses were present at the various sessions.

Dr. Newdigate M. Owensby of Atlanta, Georgia, one of the founders of the Association, and at present secretary-treasurer, reported an unusually heavy increase in applications for membership during the past year, and stated further, that the quota for fellows had already been filled.

Following opening formalities and the address of the president, Dr. William D. Partlow of Tuscaloosa, Alabama, on the morning of October 8, scientific sessions were held during the afternoon and during the morning and afternoon sessions, October 9.

Contributors to the scientific program were: Dr. George T. Harding, Columbus, Ohio, "The Periodicity of the Manic Depressive Psychoses"; Dr. Giles W. Day, Galveston, Texas, "Discus-

sion of Newer Methods of Psychiatric Treatment"; Dr. W. C. McConnell, St. Petersburg, Florida, "Endocrinology in Psychiatry"; Dr. Guy F. Witt, Dallas, Texas, "Mental Disturbance Due to Bromide Intoxication"; Dr. James A. Willie, Houston, Texas, "The Analysis of a Case of Hysteria"; Dr. Isham Kimball, Lexington, Ky., "The Necessity for Comparative Study of Schizophrenia and Organic Reaction Types of Psychoses"; Dr. Walter J. Otis, New Orleans, Alabama, "Childhood's Early Symptoms of Mental Hygiene Problems"; Dr. D. Henry Poer, Atlanta, Georgia, "Psychoses Due to Thyroid Disorders"; Dr. George Rudolph Herrman, Galveston, Texas, "Neuro-Cardiac and Neuro-Circulatory Disorders"; Dr. W. B. Russ, San Antonio, Texas, "Psychoses Complicating Surgical Cases"; Dr. Newdigate M. Owensby, Atlanta, Georgia, "Sanity in Psychiatry." Guest speakers were: Dr. Philip Smith, New York, "Psychiatric Work in New York Institutions", and Dr. C. C. Burlingame, Hartford, Conn., "Can the Point of View and Technique of Private Practice be Carried into the Mental Hospital?"

Officers elected for the coming year are: Dr. George P. Sprague, Lexington, Ky., president; Dr. Charles S. Holbrook, clinical professor of psychiatry, Tulane University, president-elect; Dr. Newdigate M. Owensby, Atlanta, Georgia, re-elected secretary and treasurer; Dr. H. W. Priddy, Memphis, Tenn., vice-president; Dr. T. M. Dorbandt, San Antonio, Texas, and Dr. W. D. Partlow, Tuscaloosa, Alabama, councillors.

The next meeting of the Association will be held in Atlanta, Georgia.

KENTUCKY PSYCHIATRIC ASSOCIATION.—On May 5, 1937, a group of psychiatrists practicing in the State of Kentucky met in Lexington for the purpose of organizing a psychiatric association. As a result of this meeting, the Kentucky Psychiatric Association was formed with the following stated objectives: "to further the study of subjects pertaining to the nature, treatment and prevention of nervous and mental disorders; to further the interests, the maintenance and advancement of standards of hospitals for nervous and mental disorders, or outpatient clinics, and of all other agencies concerned with the medical, social and legal aspects of these disorders; to further psychiatric education and research; and

to apply psychiatric knowledge to other branches of medicine, to other sciences and to the public welfare of the citizens of the State of Kentucky."

Two classes of membership are provided: "Members and Honorary Members. Members shall be residents of the State of Kentucky at the time of their election and Honorary Members shall be residents of the United States or its dependencies."

Officers were elected for the year 1937-38, and are as follows:

President: Isham Kimbell, M. D., Lexington.
Vice-President: Spafford Ackerly, M. D., Louisville.
Secretary-Treasurer: Robert H. Felix, M. D., Lexington.
Councillors:
Lawrence Kolb, M. D., Lexington, for 4 years.
W. E. Gardner, M. D., Louisville, for 3 years.
L. E. Trent, M. D., Lexington, for 2 years.
L. M. Rogers, M. D., Lexington, for 1 year.

The first annual meeting will be held in Louisville January 8, 1938.

Dr. Jung Gives Terry Lectures at Yale.—Carl Gustav Jung, M. D., LL. D., professor of analytic psychology, Federal Polytechnical University, Zurich, Switzerland, gave the Dwight H. Terry Lectures at Yale University, October 20, 21, and 22, 1937. President Seymour introduced Dr. Jung who spoke before very large and appreciative audiences. The subject of his lectures was "Applied Psychology and Religion."

The Dwight H. Terry Lectureship Fund, established in 1905 by gift from Dwight H. Terry of Plymouth, Conn., became available in 1923 for lectures on "Religion in the Light of Science and Philosophy."

Dr. Jung's lectures will be published in book form by the Yale University Press, and a review of this volume will appear later in the Journal.

DR. JOSEPH E. BARRETT TO DIRECT MICHIGAN STATE HOSPITAL COMMISSION.—Dr. Joseph E. Barrett of Taunton, Massachusetts, has been appointed director of the State Hospital Commission of Michigan by Governor Frank Murphy and the newly created Commission. The State of Michigan has adopted recently important and progressive legislation dealing with the care of the mentally ill, embodying a broad mental hygiene program and creating a central State Hospital Commission with a director as chairman.

Almost three decades ago Michigan gave her native son to Massachusetts, the late Dr. George M. Kline, who organized a Department of Mental Diseases and developed a state hospital system in Massachusetts which served as a model both in America and abroad. Dr. Barrett is uniquely qualified to consummate this reciprocal exchange with the State of Michigan because he has been trained in departmental organization and hospital management under the late Dr. Kline and under subsequent commissioners in Massachusetts including Dr. James V. May and Dr. Winfred Overholser.

Dr. Barrett was born in Jonesboro, Arkansas, April 24, 1891, and was educated in the public schools of that city and in the state university. He graduated from the University of Tennessee, School of Medicine, in 1922, and served a rotating internship at the St. Louis General Hospital. He was assistant physician at the State Hospital for Nervous Diseases, Little Rock, Arkansas, from 1923 to 1928. He was appointed assistant superintendent of the Taunton State Hospital, Taunton, Massachusetts, in 1928, was promoted to

assistant to the commissioner in the Massachusetts Department of Mental Diseases in 1931 and again promoted to assistant commissioner in 1934. He resigned from the state service June 1, 1937, since which time he has been engaged by the National Committee for Mental Hygiene in making surveys of state hospitals in Iowa and Virginia. He is a member of the Bristol County and Massachusetts Medical Societies, fellow of the American Medical Association and The American Psychiatric Association, member of the New England Society of Psychiatry, the Massachusetts Psychiatric Society, the National Committee for Mental Hygiene, and a diplomate of the American Board of Psychiatry and Neurology.

Dr. Barrett's resignation as assistant commissioner in the Massachusetts Department of Mental Diseases last June was subsequent to the replacement of Dr. Overholser as commissioner, and represents a further loss in psychiatric leadership which Massachusetts can ill afford to sustain.

SECOND INTERNATIONAL CONGRESS ON MENTAL HYGIENE.—The Second International Congress on Mental Hygiene was held at the Maison de la Chimie, Paris, opening on Monday, July 19 and concluding its program of papers on Friday, July 23.

On Saturday, the members of the Congress were taken to the main psychological laboratory of the French Railways, and later on the same day to one of the state institutions for feebleminded, ending up on that afternoon with a visit to Versailles. On Sunday, July 25, a dinner for the delegates to the Congress was held and a meeting of the International Committee for Mental Hygiene, at which meeting it was recommended that the Third International Congress should be held in 1940 in Rio de Janeiro.

On the first day of the Congress there were approximately 260 members and guests in attendance and about the same number were present on nearly all the days of the Congress. Forty countries sent representatives, and a preprinting of the papers or abstracts of the papers permitted the official delegates to have in their hands on the day of a particular meeting the papers to be presented that day with their translation. The auditorium of the Maison de la Chimie, where the meetings were held, was ample in size for the

meetings, which were all held in the auditorium of this building. One feature proved disadvantageous to the members in attendance: each paper, immediately after its presentation, was abstracted by an interpreter and given in the two other official languages of the Congress—for example, if a paper was given in German it was then abstracted in French and in English. This necessitated, for those who remained through all the sessions, the hearing of each paper, at least in abbreviated form, twice after having heard it read in full in its original language. Although the building was provided with head phones and dials so that two translators on the platform could immediately give the papers in the other official languages, these were not in use until the succeeding week at the First International Congress on Child Psychiatry. Undoubtedly, this was for reasons of economy, as when used at the Congress on Child Psychiatry, it enabled the delegates to put on the head phones, turn the dial to the language in which they wished to hear the paper, and in that way each paper was given only once, which served to expedite the program and avoid fatigue for those listening.

The opening session of the Congress had the usual addresses by the Minister of Health of France and by Dr. Edouard Toulouse, President of the Second International Congress on Mental Hygiene; also the report of Mr. Clifford W. Beers, Secretary General of the International Committee for Mental Hygiene, and a report by Dr. Georges Genil-Perrin, Secretary General of the Second International Congress on Mental Hygiene. Doctor Toulouse in his address paid a very splendid tribute to Mr. Beers as the founder of the work in mental hygiene.

In the opening session the last paper was given by Dr. André Repond of Switzerland, entitled the "Scientific Bases of Mental Hygiene." This was one of the most stimulating papers of the whole session and stressed the need for an attempt to obtain the factual data relating to problems of mental health, and to constantly strive through scientific studies to develop an adequate preventive program. On each day the morning program was usually given to three papers, each one having someone assigned for discussion of the paper. The length of the programs in general did not allow for much other discussion from the floor and there were many in attendance at the Congress, who, if time had permitted, could have made distinct contributions to the discussion. Each afternoon program

was given over to short five minute communications which were presented but no time was allowed for discussion of these communications.

The first day of the Congress, the general subject for the papers was Genetics and among those presenting papers on that day were Professor Rüdin of Munich and Dr. J. M. Sacristan of Madrid. The paper of Dr. Howard C. Taylor of New York was read in his absence by Dr. Adolf Meyer and was discussed by Professor Pohlisch of Bohn, Germany.

The second day of the Congress was given over to Mental Hygiene and Education.

One of the best papers in this series was given by Dr. Dorrado Tumiati of Florence, Italy, on "Mental Hygiene in the Education of the Family." One of the most interesting communications presented on this day was by Dr. Ruth E. Fairbank of Baltimore, taking up the problem of epidemiology of the mental hygiene problems presented in the year 1933 in a district of Baltimore, Maryland.

On the third day the morning program was devoted to a miscellaneous group of papers and communications dealing with heredity and constitution and special studies, both in prevention and treatment, of mental disease. One of the most interesting papers that day was by Professor Kretschmer of Marburg, Germany, dealing with the rôle of heredity and constitution in the etiology of mental disorders. In the afternoon the topics presented were the toxic disorders and some of the mental health problems in relation to suicide. Professor Walter R. Miles, of the Institute of Human Relations, Yale University, gave a very excellent paper discussing the Prophylaxis of Alcohol very completely; and Professor D. K. Henderson of Edinburgh presented an excellent paper on Individual and Social Prophylaxis regarding Suicide.

On the morning of the fourth day the program concerned itself with the organization of mental health facilities. The mental hygiene organizations in various communities and states were discussed and much interesting material was presented.

In the afternoon medico-legal problems concerning the psychopath and the criminal were presented.

On the fifth day the session was devoted to problems of statistics, classification and public education. Sir Hubert Bond pre-

sented a paper making a plea for international classification of mental troubles, bringing up the whole problem of nomenclature. This paper was discussed by Dr. Horatio M. Pollock of the Mental Hygiene Department of New York State.

Following the afternoon session on several of the days, visits to the psychological laboratory of the Paris Street Railway System were arranged and visits to several of the institutions near Paris for the care of the mentally sick and mentally deficient.

A series of social entertainments were provided, starting on the first of the week with a reception at the Minister of Foreign Affairs, and concluding with a reception given at the Hotel de Ville for the delegates to this Congress and those attending the Psychologic Congress which started its session at this time, as well as those who came for the First International Congress on Child Psychiatry.

As is common with all large Congresses, the opportunity to meet leaders in their respective fields throughout the world was a special privilege. Frequently divergent views were presented but usually in the discussion a common ground was found for our future method of procedure, and in the opinion of the writer this Congress did much toward clarifying our thinking on many important problems relating to mental health, strengthened materially the organization working toward this and brought together for earnest personal discussion many who are contributing greatly to the advancement of this comparatively young branch of preventive medicine.

The American delegation welcomed the presence of the Dean of American Psychiatry—Dr. Adolf Meyer, who attended every session and presided over one of them.

The Secretary of the Congress, Dr. René Charpentier, accomplished almost single handed in this Congress the problems of organization and the preparation of the programs, and deserves highest credit for his work, as well as do many others who contributed both in time and effort toward the success of the Congress.

A. H. R.

AMERICAN PUBLIC HEALTH ASSOCIATION MEETING, 1938.—The officers of the American Public Health Association announce that the 67th annual meeting will be held in Kansas City, Mo., October 25-28, 1938.

Dr. Edwin Henry Schorer, director of the Kansas City Health Department, has been appointed chairman of the local committee. He will be assisted by a large group of city and state officials and community leaders.

A long list of affiliated organizations meet habitually with the American Public Health Association. They include:

The American Association of School Physicians.
The Association of Women in Public Health.
The Conference of State Laboratory Directors.
The Conference of State Sanitary Engineers.
The American Association of State Registration Executives.
Delta Omega.
The International Society of Medical Health Officers.

The attendance at the 67th annual meeting will exceed 3000 professional public health workers from every state in the Union, Canada, Cuba and Mexico.

Dr. Worthing Appointed Superintendent of Pilgrim State Hospital.—Commissioner William J. Tiffany has announced the transfer on December 1, 1937, of Dr. Harry J. Worthing, superintendent of Willard State Hospital to the superintendency of Pilgrim State Hospital, thus succeeding Dr. Tiffany as head of the largest institution for the mentally ill in the United States.

Dr. Travis Appointed Superintendent of Willard State Hospital.—The appointment has been announced of Dr. John Henry Travis to the superintendency of Willard State Hospital to succeed Dr. Harry J. Worthing. Dr. Travis is a native of Ontario and graduated in medicine at the University of Toronto in 1911. During the war he served in the Canadian Army Medical Corps, and has been attached to the staffs of mental hospitals in Massachusetts, Maine and New York, and has recently been acting medical inspector for the New York State Department of Mental Hygiene. His appointment at Willard becomes effective January 1, 1938.

DR. ZIEGLER BECOMES ASSOCIATE MEDICAL DIRECTOR OF MILWAUKEE SANITARIUM.—The appointment has been announced of Dr. Lloyd H. Ziegler, professor of psychiatry at the Albany Medical School and head of the division of psychiatry and neurology of the Albany Hospital since 1930, to the position of associate medical director of the Milwaukee Sanitarium, Wauwatosa, Wisconsin. Dr. Ziegler will also serve on the faculty of the College of Medicine, University of Illinois.

SOCIAL HYGIENE DAY.—National Social Hygiene Day, the second observance of which has been set for February 2, 1938 by the American Social Hygiene Association, marks the high point in the year round effort to gain popular interest and support for the activities of the health authorities and the medical profession in dealing with syphilis and gonorrhea. Interested official and voluntary agencies concentrate their efforts at this time on giving the subject the widest possible publicity, by arranging for meetings of interested groups, press stories and comment, appropriate radio broadcasts, and the like.

The first National Social Hygiene Day, February 3, 1937, was an immediate success in accomplishing its purpose; it was marked by hundreds of meetings held throughout the country. More than a thousand newspaper clippings coming from all parts of the country testify to its uniformly favorable press.

"Stamp Out Syphilis—Enemy of Youth" is the slogan for the 1938 Social Hygiene Day meetings. Particular emphasis will be laid on the control of syphilis among the twenty to thirty year age group, in which more than half of all new infections occur.

Suggestions for meetings and practical community programs may be obtained from the American Social Hygiene Association, 50 West 50th Street, New York City. The Association will be glad to supply interested persons and groups with materials, such as exhibits, films, and literature.

ADVISORY BOARD FOR MEDICAL SPECIALTIES AND GRADUATE MEDICAL EDUCATION.—This Board, organized in 1933-34, for the purpose of coordinating graduate education and certification of

medical specialists in the United States and Canada, and which functions in conjunction with the Council on Medical Education and Hospitals of the American Medical Association, adopted the following resolution at its meeting in Atlantic City, June 6, 1937.

Resolved, That the President appoint four members of the Advisory Board for Medical Specialties with power to add to their number and to form a Commission on Graduate Medical Education to study the problems of graduate and postgraduate medical training, such a Commission to be comprised of representatives of the medical profession, the hospitals, the universities, the medical schools and the licensing bodies.

Dr. Willard C. Rappleye, president of the Advisory Board for Medical Specialties, reports that a Commission on Graduate Medical Education has now been created. The Commission will undertake to mobilize current opinions as to how the problems in this field can best be solved and to formulate the educational principles involved in graduate and postgraduate medical training. It is hoped that standards of training can be drawn up which will be of help to the Council on Medical Education and Hospitals and other agencies concerned with the inspection and evaluation of the facilities needed. There would be no duplication of effort nor conflict with the Council and these other agencies. The results of the studies by the Commission should be of real assistance to the specialty board, the medical profession, hospitals, medical schools, state board of medical examiners, and other institutions and organizations concerned with this phase of American medicine.

The personnel of the Commission on Graduate Medical Education follows:

Fred L. Adair, Chicago, Vice-President, American Board of Obstetrics and Gynecology.

A. C. Bachmeyer, Chicago, Director, University of Chicago Clinics; Former President, American Hospital Association.

Donald C. Balfour, Rochester, Director, Mayo Foundation Member, Board of Regents, American College of Surgeons.

Kenneth D. Blackfan, Boston, Professor of Pediatrics, Harvard Medical School.

James D. Bruce, Ann Arbor, Vice-President and Director of Department of Postgraduate Medicine, University of Michigan; Chairman, National Committee on Post-Graduate Medical Training.

R. C. Buerki, Madison, Superintendent, University of Wisconsin Hospital, Former President, American Hospital Association.

Anton J. Carlson, Chicago, Professor of Physiology, University of Chicago.

Walter F. Donaldson, Pittsburgh, Secretary, Pennsylvania State Medical Society, and former member of Council on Medical Education and Hospitals of American Medical Association.

Reginald Fitz, Boston, Member, American Board of Internal Medicine, Member, Council on Medical Education and Hospitals.

Evarts A. Graham, St. Louis, Chairman, American Board of Surgery.

F. W. Hartman, Detroit, Secretary-Treasurer, American Board of Pathology.

Willard C. Rappleye, New York, Dean, Columbia University Faculty of Medicine, Director, New York Post-Graduate Medical School; Former Director of Study, Commission on Medical Education.

J. Stewart Rodman, Philadelphia, Secretary, American Board of Surgery; Medical Secretary, National Board of Medical Examiners.

Harold Rypins, Albany, Secretary, New York State Board of Medical Examiners; Former President, Federation of State Medical Boards of United States.

Alfred Stengel, Philadelphia, Vice-President in Charge of Medical Affairs, University of Pennsylvania.

William P. Wherry, Omaha, Secretary, American Board of Otolaryngology; Executive Secretary, The American Academy of Ophthalmology and Otolaryngology.

Allen O. Whipple, New York, Vice Chairman, American Board of Surgery; Member, Committee on Graduate Teaching, American Surgical Association.

Ray Lyman Wilbur, Stanford, President, Stanford University; Chairman, Council on Medical Education and Hospitals of the American Medical Association; Former President, American Medical Association; Former President, Association of American Medical Colleges.

John Youmans, Nashville, Director of Post-graduate Instruction, Vanderbilt University School of Medicine.

SOCIOMETRY: A JOURNAL OF INTER-PERSONAL RELATIONS.—This is a new journal, edited by Gardner Murphy, Ph. D., of Columbia University and published by J. L. Moreno, M. D., physician in charge, Beacon Hill Sanitarium, constitutes a fresh attempt to integrate the social sciences. The ingredients that go into the attempt are rather diverse and the synthesis of these ingredients is at the present time obscured. Sociometry is defined in the editorial foreword as the embodiment of a "device for ascertaining and measuring the positive social responses of each individual to each other individual in his social world, a means of describing the degrees and forms of intimacy longed for by each person in relation to each of his fellows" (pp. 6-7). Whether it is a fruitful device for so

doing can only be decided by the future. Whether *sociometry* is a good word to describe such a device is likewise problematical. Insofar as it is an attempt to reduce inter-personal relations to a quantitative basis of formulation, it is merely another attempt to do what all good sociologists since Comte have tried to do. As the quotation shows, however, it is more than reducing human relationships to diagrams. The words "response" and "longed for intimacy" imply a systematic framework within which the relationships are viewed. And as these are psychological words it is obviously a psychological framework. The value of the framework and the method generally can only be tested by its research results, not by *a priori* arguments as to whether, for example, response is the individual counterpart of the biological term adaptation.

The viewpoint of the contributors to *Sociometry* has certain initial advantages over other attempted integrations of social and human studies. It is grounded firmly on two propositions which are stressed again and again—*man* is a creature of his environment and *a man's* environment includes all other men with whom he is intimate. This is a stress badly needed to bring medical and social studies together. The social scientists is too apt to forget the first and the biological scientist to forget the second. Insofar as this new journal refuses to judge between them and emphasizes the importance of both, the part it can play in bringing the two wings together is obvious and its future ought to be assured.

First International Congress on Child Psychiatry.—The first International Congress on Child Psychiatry was held at the Maison de la Chimie, Paris, from the 21st of July to the first of August. The Congress was a very notable success, approximately 300 delegates attending each of the sessions, and 26 countries were officially represented. All the sessions were conducted by the President, Dr. G. Heuyer, and the Secretary-General, Dr. Leon Michaux. The official welcome was given to the Congress by the Minister of Public Health.

The first day of the Congress was devoted to a consideration of the neuro-physiological factors in child psychiatry.

On Sunday, the second day, a visit was arranged to the laboratory of the University and to a children's colony at Perray-Vaucluse where sub-normal and problem children are cared for.

On the third day of the Congress papers were devoted to the problems of the conditioned reflexes. One of the most interesting papers given on this day was presented by Professor Marianesco of Bucharest, Roumania, in which he pointed out the difficulty of the study of conditioned reflexes in the abnormal child, stating that he considered this an important approach toward the grouping of the nervous child, but an extremely complicated one which needed much further scientific work for a more practical development.

The fourth day was devoted to problems in education and a number of excellent papers were presented. On this day one of the outstanding papers was given by Dr. Andre Ombredan of Paris concerning a study of reading and speech disabilities in children.

On the fifth day the subject under discussion was juvenile delinquency and on this day America was represented by Dr. William Healy who gave an excellent paper concerning the work of the Judge Baker Foundation Center in Boston.

On the final day a visit was arranged to the Medico-Pedagogic Institute, d'Yvetot and an excursion in the valley of the River Seine.

This Congress brought together for the first time leaders of child psychiatry from the whole world. It did much to clarify our thinking on childhood problems and was especially helpful in emphasizing the need of scientific methods in these studies and stressing the importance of our educational procedure in the problem of childhood mental health.

The President of the Congress, Dr. Georges Heuyer was especially to be congratulated on the excellent organization of the Congress, the fine attendance and the valuable discussion that was promoted during the meetings.

A. H. R.

PSYCHIATRY: JOURNAL OF THE BIOLOGY AND THE PATHOLOGY OF INTERPERSONAL RELATIONS, is announced to appear about February 1, 1938, and quarterly thereafter. The William Alanson White Psychiatric Foundation, the publisher, states in part: "Psychiatry, as a basic discipline relating to all significant phases and problems of human life and to all human relations, needs at this time a channel of expression that will communicate its growing

insights to a wide audience of those who can make valid contributions to its data, and correct use of its formulations. The wise dissemination of psychiatry was a major interest of Dr. William A. White. The Trustees of the Foundation created to perpetuate his work, developed under his direction, and led in its first years by him, now present as one of their efforts to discharge the responsibility vested in them, a quarterly journal directed not alone to psychiatrists and psychiatric research personnel in the narrower sense, but to all serious students of human living in any of its aspects, and to those who must meet pressing social needs with current remedial attempts." Drs. Harry Stack Sullivan and Ernest E. Hadley and Mr. Thomas Harvey Gill are listed as the Editorial Committee (of the Board of Trustees). The office of publication is shown as 1835 Eye Street, N. W., Washington, D. C.

Book Reviews.

GERICHTSARZTLICHE DIAGNOSTIK UND TECHNIK. Besonders auf dem Gebiete Der Behordlichen Sektion. By *Dr. H. Merkel and Dr. K. Walcher.* (Leipzig: Verlag von S. Hirzel, 1936.)

One may wonder why a note on a textbook on forensic medicine should find its way into the pages of a psychiatric journal and yet it may not be out of place if one bears in mind the difficulties with which the institutional physician and the pathologist are faced. Not infrequently are they confronted with sudden and non-accountable deaths, with suicides and with deaths of violence. To ascertain the exact cause of such deaths is particularly important in institutions supported by public funds such as state hospitals. This volume will be of great help to the pathologist in every psychiatric hospital, and, for that matter, in any other hospital. Both the clinician and the pathologist will find in it a wealth of useful material. It offers systematic and orderly methods in search for the cause of death, based on the most recent progress in the fields of toxicology, chemistry, morphology, etc. A translation into English would be desirable.

J. NOTKIN, M. D.,
Poughkeepsie.

THE PATIENT AND THE WEATHER; CARDIO-VASCULAR-RENAL DISEASE. Vol. IV, Part 1. By *William H. Petersen, M.D.* (Ann Arbor: Edwards Brothers, 1937.)

In accordance with the Hippocratic thesis expounded in previous volumes, Professor Petersen proceeds to develop the concept that, if disease manifestations can be provoked by disturbances in the atmospheric circulation, organic disease can be shown to be referable to such causes. Always the organism is in a state of flux as it responds to varying environmental demands. It is balanced in health, unbalanced in disease. In the production of any or all of the innumerable organic lesions, actually only a limited number of mechanisms have been operative; in all instances, the basic causative factor is oxygen deficiency of varying grades of severity or duration. The greater part of the 663 pages of this volume is given over to careful case reports, tending to demonstrate that the meteorological factor may underlie the very beginning of the degenerative diseases, such as diabetes, nephritis, etc. These diseases are fundamentally of the storm tracks (as has been shown by C. A. Mills, and others), but Dr. Petersen again takes occasion to stress the fact that the meteorological factor is only one conditioning factor in a constellation of events, albeit an important one, influencing every dis-

ease just as it influences every physiological process. This work deserves the most thoughtful consideration because it serves to throw proper emphasis upon an element in disease production which has been sadly neglected since it was first expounded by the Father of Medicine. Dr. Petersen builds up a strong case to prove that "the self-same mechanism that precipitates the final clinical symptomatology is of significance in initiating the earlier disturbances of integration that ultimately cause the clinical entities that we recognize as disease."

The format is as interesting as the text; it is a beautiful example of the lithoprinter's art, while the illustrations and figures are excellent.

FAMILY CARE OF MENTAL PATIENTS. A REVIEW OF SYSTEMS OF FAMILY CARE IN AMERICA AND EUROPE. Editor: *Horatio M. Pollock, Ph. D.* Contributors: Edgar A. Doll, Ph. D.; Harry A. LaBurt, M. D.; Phillip Smith, M. D.; Charles E. Thompson, M. D.; Charles L. Vaux, M. D. (Utica, New York: State Hospitals Press, 1936.)

One or two sentences in the foreword of this little book are of great import. "This is the first book written in the English language on the subject of family care of mental patients."—"The aim in the preparation of the book has been to present clear pictures of the various systems of family care, to show their advantages and disadvantages and to set forth the opinions of officials in immediate contact with patients and guardians."

Of the eleven chapters in the book, Dr. Pollock has himself written six, while the other five are by men who have special knowledge of the situations described, but all are so correlated as to give the reader clear pictures of family care of mental patients of various types in some of the states of America and some countries of Europe.

One is struck by the tremendous success of the Colony at Gheel in Belgium, which really goes back many centuries, but which since 1852 has developed a boarding out system which surpasses that of any other country in the world. Provision is made for the family care of 3,000 patients and the annual movement of population is about 500 patients. Approximately 25,000 patients have passed through the colony in the past 60 years. The particular plan in use there is described in detail and is illustrated with splendid photographs. Why has the colony plan succeeded in Belgium so much better than in any other country? What factors have built up a state of mind among the Belgian people to adopt this system? Surely it is worth careful study from many angles. From the financial standpoint alone it is estimated that family care of state wards can be provided at about one-half the institutional cost and that about twice as many patients can be cared for annually. And what about the great advantages to the patient resulting from this type of care?

Then go back to Dr. Pollock's introductory chapter which deals with the yearly increasing numbers of mental patients—about 4½ per cent annually—

the cost of equipment and upkeep, and suggestions for developing family care based on the Gheel plan.

All the chapters are well written, and the facts learned from the various colonies described show in every case advantages socially, economically and educationally to states which have adopted this system. Concise, yet not sacrificing detail, this book may be read alike by psychiatrists and by the general public and all those who are charged with the responsibility of the care of the mentally ill.

University of Toronto.

Bewusstseinstypen und ihre Beziehung zur Psychopathologie. By *Dr. J. H. van der Hoop*, Dozent für Psychiatrie in Amsterdam. (Bern: Medizinischer Verlag Hans Huber, 1937).

Dr. van der Hoop's book attempts in a sense an amalgamation of the teachings of Freud and Jung. The author was first analyzed by Jung and later by the Freudian method in Vienna. He takes the stand that it is necessary to make a structural as well as a dynamic analysis of the person. He does not find either method entirely acceptable and modifies them to a slight degree according to his own opinions and experiences.

He differentiates, essentially following Jung, instinct, intuition, thinking and feeling, and accordingly the instinctive, intuitive, thinking and feeling types. All of these and their complications and interrelations are discussed in the first part of the book.

In the second part of the book the author shows how these types can be utilized in psychiatry. He discusses the types in relation to complexes, to neuroses, to psychopathy and to psychoses. In all of these discussions he tries to do justice to the psychoanalytic school of thought, emphasizing that in the treatment of neuroses he is using particularly the Freudian method.

In the concluding part the author presents philosophical considerations. He tries to show how far psychology can be objective and how far it is bound to be subjective, and how, in his opinion, it is possible to reconcile these seemingly contrasting points of view. Then he remarks on unity and transcendence of consciousness. Ultimately he writes on the "personal equation" using as examples the personalities of Freud, Jung and himself.

This is a thoughtful book written by a well experienced, cultured psychotherapist. Although the discussions are sometimes a bit long-winded, it is worth one's while to study this book in which time and time again remarks are found which show unusual insight into structure and dynamics of the personality.

This reviewer feels that the book would be more useful if it had an index.

Eugen Kahn,
Yale University.

THE ETIOLOGY OF MENTAL DEFICIENCY WITH SPECIAL REFERENCE TO ITS OCCURRENCE IN TWINS: A CHAPTER IN THE GENETIC HISTORY OF HUMAN INTELLIGENCE. By *A. J. Rosanoff, L. M. Handy, and I. R. Plesset.* Psychological Monographs, Vol. XLVIII, No. 4. (Princeton: Psychological Review Publications, 1937.)

The principal material on which this study is based consists of 366 pairs of twins with mental deficiency in one or both of the twins in each pair. There is also control material consisting of twins of normal and superior intelligence, groups of siblings, etc.

All degrees of mental deficiency are represented, and in many of the cases the mental deficiency is complicated with infantile cerebral palsies, epilepsy, psychotic manifestations, child behavior difficulties, juvenile delinquency or adult criminality.

The presentation is in nine sections, three of which are devoted to detailed reports of all the cases, dealing, respectively, with monozygotic twins (126 pairs), same-sex dizygotic twins (101 pairs), and opposite-sex twins (139 pairs). There are also some tables in which the main findings yielded by the study have been summarized.

The authors' evaluation of the material is presented mainly in section 7, devoted to *a theory of mental deficiency:*

Hereditary determination of intelligence is one thing, and hereditary factors in the etiology of mental deficiency are another thing. They require separate discussion. The available data seem to indicate that hereditary factors determine merely the potentially maximal intellectual development that may be attained by a given individual. In order that this potentiality may be fully realized certain conditions are requisite, the most important of which are the following: (a) There must not be a germinal damage, particularly to the ovum, such as may produce mongolism or possibly some other form of relative or absolute (*i. e.*, pathologic) mental deficiency. (b) In the embryonic period there must not be any condition interfering with normal development and producing meningocele, encephalocele, or other cranio-cerebral pathology. (c) In the fetal period there must not be any condition interfering with normal growth and resulting in premature expulsion of the fetus, or giving rise to the necessity or a forced delivery, or causing, at full term, an immature and markedly underweight condition of the fetus. (d) In the intranatal period there must not be, by reason of dystocia from any cause, or of prematurity or immaturity, or of poor obstetric technique, a cerebral birth trauma. (e) In postnatal life, especially in infancy and childhood, there must not be a head injury, or meningitis, encephalitis, or other infection with cerebral involvement. (f) In postnatal life, too, there must be such home, school, and general life environment as would foster, stimulate, and provide full opportunity for intellectual development. It is a question whether all these conditions are fulfilled for more than a limited minority of individuals in contemporary society. It is, therefore, also a question whether, in the average case, the results of our intelligence tests represent the full measure of hereditary intellectual endowment, or merely an

expression of relative, if not absolute, mental deficiency attributable to one or more non-hereditary factors. In a given case there is hardly a possibility of being quite assured on this point, even though the case be one of superior intelligence. In a given case the assurance is merely to the effect that the inherited intellectual endowment is at least as high as is indicated by the results of an intelligence test, but may be higher. The existence of relative mental deficiency in persons of normal or even superior intelligence is demonstrated not infrequently in monozygotic twins. In cases of markedly unequal intelligence it must be assumed that the hereditary intellectual endowment is represented at least by the I. Q. of the more intelligent twin of the pair. Among the hereditary factors of intelligence apparently must be counted a sex-linked factor. It would appear that scarcely more than one-half of the cases of mental deficiency are of hereditary origin. We have shown elsewhere that germinal factors were the sole cause of mongolism. Perhaps the most outstanding general result of our study consists in the importance of cerebral birth trauma in the etiology of mental deficiency and of certain complicating conditions with which it is often associated, an importance which has heretofore not been fully appraised. In our material there are barely a half-dozen cases in which postnatal factors are mentioned as possible causes. This is in harmony with general experience. Apparently such factors play but a minor rôle numerically. The bulk of mental deficiency exists from birth. In view of the rather overwhelming evidence indicating that, save in cases of mongolism, the principal non-hereditary factor in the etiology of mental deficiency is cerebral birth trauma, our data almost force the conclusion that cerebral birth trauma is capable of producing now mental deficiency, now an infantile palsy, now epilepsy, now certain types of psychotic disease, now, with significant frequency, a combination of any two or more of these conditions. Whether in a given case a cerebral birth trauma shall result in stillbirth, or in death in the neonatal period or in early infancy, as it often does; what degree of mental deficiency it shall produce; whether it shall give rise to one or another of the above-mentioned complicating conditions; whether it shall produce but a relative mental deficiency, *i. e.*, leaving behind an intellectual capacity which is still within normal limits; or whether it shall leave the subject without damage to his neurologic or intellectual function, are, presumably, matters determined by the nature, extent, and localization of the brain injury and by the course of the subsequent tissue reaction.

AUTHORS' REVIEW.

LATER CRIMINAL CAREERS. By *Sheldon and Eleanor Glueck*. (New York: The Commonwealth Fund; London: Humphrey Milford, Oxford University Press, 1937.)

The publication of "500 Criminal Careers" in 1930 marked the beginning of a series of monumental contributions by the Gluecks to our knowledge of what becomes of discharged prisoners. In that volume, based on detailed and first-hand studies of the careers of 510 prisoners during the five year

period immediately following the expiration of their sentences (1921-22) to the Massachusetts Reformatory, it was demonstrated that the oft repeated optimistic statements of officials concerning the proportion of parole successes (sometimes given as 80 or 90 per cent) were not at all consistent with the facts; that, indeed, nearly 80 per cent of the ex-prisoners had relapsed into delinquency during the period studied! Similar studies have since been made by the Gluecks upon the results of juvenile court treatment ("1,000 Juvenile Delinquents") and of treatment in a reformatory for women ("500 Delinquent Women").

The present volume, like the others, is a valuable one. It deals with the very men studied in "500 Criminal Careers" during their second five year year post-parole period, or at least with the 454 survivors of that group, with a particular view to ascertain the effects of the passage of time upon conduct, what are these influences of increasing years, and what are the effects of the social transformations which come as time goes on.

In general, they find that there has been among the ex-prisoners studied, an upward trend during the period under study, in environmental circumstances, in family relationships, in industrial adjustment, and in the use of leisure time. No general improvement has been noted in the manner of meeting economic responsibilities (the depression was quite likely a factor in this regard). A considerable improvement in the criminal conduct of the group is noted—32 per cent were non-delinquent during Period II, as compared with 21.5 per cent during Period I (the first five year post parole period). This trend has been upward even during the second period; in the fifth year of the period 42.7 per cent of the men had become non-delinquent (p. 76). No conclusion as to the causal effect of the upward economic and social trends is drawn, however, the authors contenting themselves with the statement that (p. 87) "Good family relationships, the assumption of economic responsibilities, successful industrial adjustment, and wise use of leisure, in large measure accompany non-delinquency."

One of the most interesting findings is a modified verification of the impression that criminality tends to diminish after the third decade of life. Statistically the authors find that "aging is the only factor which emerges as significant in the reformative process," and therefore infer that "the principal explanation of the reform which has occurred in one group is to be found in that factor" (p. 105). In the 31-35 year group the increase in non-delinquency increased from 14.7 per cent at the beginning of Period I to 34.3 per cent for the beginning of Period II. This increase is cumulative, since the reformation of a considerable number had occurred in the third decade of life. Apparently after the age of 36 reformation "declines and dwindles to almost nil" (p. 106).

Of especial interest to the psychiatrist is the weighty importance of mental abnormality—in the broader sense—as an impediment to reformation. In fact, "in nine-tenths of these cases the failure of the men to improve appeared, on consideration of the factors and mechanisms in each case, to be clearly due to some mental or marked personality abnormality—psychosis, psychopathic personality, alcoholism, sex perversion, drug addiction, great emotional

instability, and the like" (p. 125). The diagnoses have reference to the condition at the time of admission to the reformatory (about 20 years ago), not to the present diagnosis. (Most of the diagnoses were made by Dr. Guy G. Fernald, one of the pioneers in the field of psychiatry as applied to correctional institutions.) Mental deficiency or retardation was considered separately, and was found to play a much less important rôle than mental deviation. The increasing importance of the factor of mental deviation is emphasized in chapter XII, on "Predicting Criminal Conduct."

In "500 Criminal Careers," the most thorough scientific attempt up to then was made to establish a prognostic table by use of the statistical method of the "coefficient of contingency" (see p. 181-2, that volume). Of the six factors then employed, mental abnormality on entrance to the reformatory was number six in order of rank of coefficients. Employing the data developed in the present study and thus taking advantage of a ten year observation, mental condition is found to be easily the most predictive of the five pre-reformatory factors employed in the present prognostic table. The coefficient of contingency has increased from .26 in Period I to .43 in Period II, the next highest coefficient in the table (work habits) being .35.

The construction of prognostic tables such as those which have been carefully elaborated by the Gluecks represents one possible contribution of statistics to penal administration. The authors emphasize the fact that no such table is meant to be mechanically applied; on the other hand, the "objectified and organized experience with hundreds of similar cases" can lend valuable aid to the exercise of discretion. Would that more parole boards were able, by training and intelligence, to profit by such pearls as the Gluecks have spread before them in abundance!

One lesson from this study is the need for a completely indeterminate sentence or a broad zoned one (one with a wide spread between maximum and minimum) to cover all serious offenders, together with a "more scientific parole policy and technique enforced by a trained personnel" (p. 207). The possibility of new procedures, too, is suggested, such as a more intelligent and realistic dealing with the chronic alcoholic. Finally, the desirability of a "treatment tribunal" is urged once more—a concept which is gaining steady ground among students of the law. The chance, indeed the assurance, that changes such as those urged would be far more effective and less expensive than the present method hardly needs to be argued.

Copious appendices, on method, definitions, code-table index, period comparison tables, correlation tables, and comparison of percentages of non-delinquency in Periods I and II are provided. In this manner, ample supporting data are ready to hand for any temerous enough to doubt the Gluecks' statistics or to try to add to them!

The volume is a substantial addition to our knowledge of the graduates of our correctional (?) institutions, and should be closely read by every one seriously interested in improving the present all-too-ineffective mechanisms whereby society attempts to deal with those who come into conflict with its laws.

Washington, D. C.

FOURTH ANNUAL REPORT OF MENTAL INSTITUTIONS. DOMINION OF CANADA. (Ottawa: Dominion Bureau of Statistics, 1935.)

This report represents a summary of the significant data concerning mental institutions in Canada for the year 1935, along with some comparative data for each of the four years (1931 to 1935) for which a similar report has been made. It is the fourth in a series of analyses of significant data in connection with mental institutions in Canada.

The report is presented in two sections. Part I deals with administrative aspects, general statistics of movement of patient population and statement of finances in all mental institutions in Canada. Part II includes special and detailed information in the form of tables covering first admissions, readmissions, discharges, transfers and deaths in public mental hospitals, together with detailed classifications of the various psychoses of patients and a large body of other important data made available by the card system which is now in use in thirty-one public mental hospitals in Canada.

There were 56 institutions in Canada at the close of the year 1935, of which 36 were maintained and controlled by provincial authorities, 14 by counties and municipalities, 2 were under the management and control of the Dominion Government and 4 were conducted by private agencies. Of the 56 institutions, Prince Edward Island and New Brunswick each had one, Saskatchewan had two, Alberta, Manitoba, and British Columbia each had four, Quebec had nine, Ontario had fifteen, and Nova Scotia had sixteen. There are two institutions less than there were in 1934, Ontario and British Columbia each having one less.

There is a marked increase in patient population in institutions in 1935 as compared with that of 1934. The total number of patients on the books of these institutions on December 31, 1935 was 41,216 as compared with 39,097, the total number of patients on the books on January 1, 1935. There were 10,869 admissions in 1935. The daily average resident patients for the year 1935 was 38,052 as compared with 36,571 in 1934. There was an increase of 4.3 in the number of mentally ill in residence. The provinces of Alberta, Nova Scotia and Ontario showing the largest increases, Prince Edward Island showing the smallest increase and British Columbia the only province showing a decrease. The proportion of patients in residence per 100,000 was 348.2 at the end of year 1935 as compared with 335.6 for 1934.

There is some information with regard to overcrowding which indicates a rather serious situation. In 1931 the normal bed capacity was 31,832 and the patients in residence, 31,686. In 1935 the normal bed capacity was 35,987 and the patients in residence, 38,261; with a per cent of excess over capacity of 6.3. While the normal bed capacity in 1935 represents a 13 per cent increase in bed capacity over that of 1931, the patients in residence at end of the year 1935 show an increase of 20 per cent during the same period.

There were 10,869 direct admissions in the year 1935, of which 8,703 or 80.07 per cent were first admissions and 2,166 or 19.93 per cent were readmissions. This shows an increase of 10.02 per cent for first admissions and

13.64 per cent for readmissions over that of 1934. Of the first admissions, 78.7 per cent were classed as insane. Of those, dementia præcox and manic depressive constitute the two largest groups, with 21.7 per cent of total first admissions for the former, and 12.9 per cent for the latter. The dementia præcox group shows a decrease of 1.4 per cent as compared with 1934. The number of first admissions in the non-psychotic group has shown a steady increase each year of the four-year period. Of the readmissions, 29.2 per cent were in the manic depressive group and 28.4 per cent were in the dementia præcox group. There were 4,356 patients discharged from hospitals, of which 1,216 or 27.9 per cent were discharged as recovered, 2,160 or 49.6 per cent as improved, 275 or 6.3 per cent as without psychosis, 687 or 15.8 per cent as unimproved, and 18 or 0.4 per cent as unclassified. The deaths numbered 2,192.

The total personnel for the 56 institutions was 7,017. The personnel in the 39 institutions devoted exclusively to the care of mental patients totalled 6,383, which was an average of 5.7 patients for each employee, an average of 172 patients to each physician, and an average of 44.9 patients to each graduate nurse.

The total expenditure for the 39 hospitals devoted exclusively to the care of mental patients was $9,659,274.27, of which $7,960,187.42 was used for maintenance expenditures and $1,699,086.85 for non-maintenance expenditures.

The significant figures, I think, are those which indicate a steady increase in the number of patients in residence from the years 1931 to 1935. There were 31,686 patients in residence in 1931; 32,878 in 1932; 34,979 in 1933; 36,571 in 1934; and 38,261 in 1935. There is no conclusive evidence as to the cause for this increase, but it is stated that, "Whatever causes may be assigned to this continual rise in the mental hospital population, it is evident that the demand for accommodation in our mental hospitals has become a pressing problem and gives some grounds for anxiety."

THE INTELLECTUAL FUNCTIONS OF THE FRONTAL LOBES. (A STUDY BASED UPON OBSERVATION OF A MAN AFTER PARTIAL BILATERAL LOBECTOMY.) By *Richard M. Brickner, B.S., M.D.* (New York: Macmillan Co., 1936.)

Doctor Brickner and his collaborators have carried out an exhaustive study of a patient who had had most of both frontal lobes removed. Doctor Dandy operated on the patient and carried out the resection of the frontal lobes to gain sufficient exposure to permit the complete removal of a large midline meningioma. As the tumor was completely removed, and also because there was no evidence of increased intracranial pressure at the time the studies were made by Doctor Brickner, it is reasonable to assume that mental variations from the pre-operative state were due to the bilateral loss of frontal lobe tissue, rather than to abnormal functioning of the remaining brain tissue.

A large part of the book is given over to a verbatim report of conversations which the patient had in various surroundings with different people. These conversations have been grouped in a well thought out scheme to illustrate different mental defects. Doctor Brickner analyses this material in an interesting and capable manner, however the studies are reported in sufficient detail to enable the reader to draw an independent conclusion.

Doctor Brickner concludes that the primary defect was a diminution in the ability to synthesize, thus placing a limit upon the degree of attainable complexity of thought. The patient showed lack of restraint in even ordinary situations and was incapable of adequate adjustment to his environment, requiring constant supervision.

An important surgical conclusion to be drawn from this one case is that bilateral frontal lobectomy should never be done. This is in contradistinction to unilateral frontal lobectomy which has been performed many times and with satisfactory results, provided there is no great involvement of the other frontal lobes by tumor.

The care and detail which has been expended in the study of this case is to be highly commended. The book is very readable and will remain of great interest to neurologists, psychiatrists and others who are desirous of gaining more knowledge concerning the function of the frontal lobes.

University of Toronto.

CHILDREN HANDICAPPED BY CEREBRAL PALSY. By *Elizabeth Evans Lord.* (New York: The Commonwealth Fund; London: Humphrey Milford, Oxford University Press, 1937.)

This book represents an effort to summarize experience gained from the examination and follow-up of more than 300 cases of cerebral palsy. With few exceptions these cases were studied at the Children's Hospital in Boston. Particular attention is given to practical methods of psychological diagnosis and prognosis in relation to home management, muscle training, and more formal scholastic education.

Dr. Crothers has given in Chapter I an explanation of cerebral palsy and a glossary of medical terms for those unfamiliar with the neurological implications of the diagnosis. It seems to the reviewer that Dr. Crothers underestimates the capacity of his readers and sometimes diverges from fact. For example, he says: "The essential point is that cerebral control of the activities of the body can be divided roughly into: (a) control of balance from the cerebellum; (b) control of associated movement which can be attributed to the basal ganglia; (c) voluntary control from the cortex." This is too simple to be true. Moreover a great opportunity is lost when Crothers so grossly abbreviates his neurological observations. Two or three chapters of great importance could well have gone in at this point setting forth the correlations between the observations of the neurologist and those of the psychologist on this unique group of children. It is hoped that Crothers is only biding his time and will later produce this data.

Chapter II presents a brief discussion of the psychological aspects of the treatment of physical disability. Directed voluntary activity, such as exercises and games, and methods of securing relaxation and developing muscular control are described. The measurement of results in terms of the increased efficiency of the child is also discussed. The further development and use of such practical standards of comparison will lead, it is hoped, to earlier and more accurate prediction with respect to the child's future degree of physical independence. Changes in physical efficiency by which a child moves from dependent to semi-dependent to independent activity, have a profound effect upon an educational program. This chapter would be improved by making the statements somewhat more categorical; the author is so cautious that she could be charged with circumlocution. Also, figure three would be improved by a graph showing normal development with which to compare the graphs of the motor development of the eight disabled children.

A method of appraising the mental status is found in chapter III. Instead of attempting to describe the mental capacity of a child in terms of a general intelligence level, test situations have been selected that will indicate abilities and disabilities in relation to chronological age and variations in achievement. Through repeated examinations it must lead to a prediction of educability. If the testing program is to have any practical value, it must bring out these variations in achievement, so that parent, doctor, and teacher can understand why a child who seems bright to one person seems stupid to another. Some interesting observations on reading defects are mentioned. In these children there are evidently syndromes of agraphia, alexia and acalculia not seen by the general neurologist. The emphasis on "focus" and "visual field" defects seems wrong to the reviewer. It is more likely that the defects are in the comprehension of symbols.

There are many aspects of behavior which can be considered as indications of intelligence. In chapter IV these are discussed in relation to the mental test situations. Mental tests have value insofar as they offer an objective explanation of the differences of opinion which almost inevitably arise in connection with a handicapped child. Significant findings on repeated examiation are presented and three characteristic types of mental development are described: (1) Those cases in which the mental development was consistent and progressed at a constant rate. (2) Those cases where the tests revealed a demonstrable and relatively rapid advance in mental development during the early preschool years, but later showed retardation. (3) Cases in which the irregularities in mental development gave a behavior picture that is difficult to appraise and still more difficult to interpret to doctors, teachers, and parents as the usual terms—mental age or mental level—did not apply. In the situations dealing with language the child may show an adequate, even advanced, vocabulary for his age. In contrast to this ability in the use of language, he may have the disabilities: he may show poor discrimination of form, varying from a difficulty in distinguishing between letters to a failure to recognize pictures. He may also show an inability to reproduce the direction of lines. This difficulty is not due to incoordinate motions that prevent the

grasping or retention of a pencil, but seems to be based on a kinaesthetic defect which hinders the appreciation of the motion required to produce the desired result. Difficulties in number concept in the preschool years indicated difficulty in arithmetic later. With these irregularities in achievement, it is not strange that a wide range of opinion as to the child's mentality is often expressed and the parents stand perplexed in the midst of conflicting advice. Mental tests have clinical value insofar as they present an objective analysis of the mental condition, which by its clarity will reduce the conflict of opinion and give a sound and convincing basis for educational plans.

The teacher's problem is briefly sketched in chapter IV, and some of the emotional problems of mother and child are discussed in chapter V. Through the early months many spastic children are feeding problems, and poor habits of eating and sleeping are set up which are later difficult to change. These children are a severe strain on the parents, but if at an early age they can be conditioned to a regular routine they may lead happy lives. The more defective children are easier to handle because they accept life with equanimity.

Much thought is given to the correct approach to the parent. Sometimes it is easy to explain the true situation to them. More often the parents, listening to the report in a highly emotional state of mingled fears and hopes will reject the painful ideas and cling to whatever they can interpret as encouraging. It is highly desirable that the person explaining the diagnosis should obtain in the initial contact as clear a picture as possible of the parent's fears and hopes and of the meanings they have attached to the words used in diagnosis. He can then use their language and avoid confusion. Advising institutional care is most difficult. Even though commonsense and regard for other members of the family indicates clearly the necessity for institutional care, the mothers usually insist on looking after the child at home, so the physician must watch her and try to protect her from useless self-sacrifice, and harmful sacrifice of other children.

The book is brief and to the point. It contains much useful information and pertinent advice for neurologist, pediatrician and psychologist.

THE MORPHINE HABIT AND ITS PAINLESS TREATMENT. (2nd edition.) By *G. Laughton Scott.* (London: H. K. Lewis & Co., Ltd., 1937.)

This book describes a method of withdrawal treatment designed to ameliorate the abstinence phenomena which occur when morphine and its derivatives are withheld from addicts who have become dependent upon them. The author claims that with the use of this method withdrawal is "painless" and he attributes this to his technique of administering Lambert's "special mixture" (2 parts 15 per cent tr. belladonna, 1 part fld. ext. hyoscyamus, and 1 part water). This technique involves the administration of small doses (5 to 60 minims) of the "special mixture" hourly for several days, together with large doses (2 to 15 grains per day) of "luminal," while morphine is

being rapidly reduced. The object of this dosage technique is to develop a high belladonna tolerance in the patients. The author feels that he can thus maintain "constant vagal preponderance," and that this corrects the sympathetic-parasympathetic imbalance which occurs during withdrawal. The maintenance of a normal pulse rate is the criterion of "special mixture" dosage: increases in pulse rate indicating that the increases in dosage have been too great. The treatment of three cases is described, and summaries of 20 consecutively treated cases are presented. The criterion of successful treatment is freedom from subjective withdrawal discomfort.

In none of the cases was the presence of physical dependence established prior to the administration of the treatment; no control data are presented for comparison of this treatment with (1) rapid reduction only, (2) rapid reduction with only "luminal," or (3) rapid reduction with only "special mixture"; and no description is given of objective manifestations of abstinence exhibited by patients receiving this type of therapy.

The atropine equivalents of the total amounts of "special mixture" administered per day (assuming that only 10 hourly doses were given daily) would range from 1.25 to 15 mgm. Sollmann (A Manual of Pharmacology, 4th edition, page 394) states that ". . . . the continued use of small doses (of atropine) establishes partial tolerance to the toxic action, but not to the effects on the vagus or occulomotor." Any manifestation of augmented vagal tone would, therefore, be difficult to conceive of in the presense of paralysis of the peripheral distribution of the cranio-sacral autonomic nerves. A more tenable explanation would seem to be that this treatment probably utilizes the maintenance of sub-toxic atropinization while the patient is undergoing a sensible rapid reduction. The use of large doses of "luminal" would seem to indicate lack of the specificity of the "special mixture" for amelioration of abstinence phenomena.

U. S. Public Health Service.

Reading, Writing and Speech Problems in Children. By *Samuel Torrey Orton, M. D.* (Thomas W. Salmon Memorial Lectures.) (New York: W. W. Norton & Co., 1937.)

This is an important monograph because it sums up ten years' work and gives Orton's recent conclusions. His principal thesis is that there are striking inherent or constitutional differences in certain children, apart from those of general intelligence, which influence their acquisition of the language function. It is toward a better understanding of these differences and their treatment that the studies which are reported in this volume were directed.

The neurological background is covered in chapter one where there is a brief discussion of aphasia and laterality. Concerning handedness he states: "The great degree of individual variation which has become increasingly apparent as our studies of laterality have progressed makes it clear that no dogmatic general answer can be given to the question as to whether a left-handed child should ever be trained on the right side. The question can be

answered only for a given individual after tests and observations of the child himself, and even then it is sometimes necessary to experiment with a period of training and, in one or two instances, such an experimental period demonstrated that our first opinion based on history and tests was not leading to the expected results in training and it was necessary to change the program completely. One other factor which must be considered here is the age of the child. As will be elaborated in a subsequent chapter, there are certain periods in a child's development—notably between two and three, and six to eight years of age—which are critical in the development of the language function, and interference with inherent handedness patterns at these times seems much more prone to give rise to difficulties than at others."

Developmental alexia is discussed at length. It is a sensory disorder, primarily a difficulty in the recall of word pictures. It is synonymous with congenital word blindness, strephosymbolia or, more simply, specific reading disability. Being sensory, it is not associated with handedness, either right, left or crossed patterns, but there are an unusual number of the latter found among these children (*i. e.*, right-handed and left-eyed). Combined with developmental alexia, or independently, one finds the syndrome of developmental agraphia. This is the most specific of the syndromes described. It is a special writing disability usually the result of faulty training, an enforced shift of handedness or marked "motor intergrading" (lack of preferential choice of a master hand). Developmental word deafness is a more rare, but more severe condition, difficult to recognize because of its superficial resemblance to general lack of intelligence. Left-handedness is present in "most" of the families of these children, and the child himself often shows motor intergrading. Developmental aphasia and apraxia are very rare, and apparently are included for orderliness and completeness of exposition.

Stuttering is only briefly discussed, the author believes that the speech defect causes so many social difficulties that a great emotional overlay is accumulated. "The emotional and personality factors which are so striking later and which have led many observers to classify all stutterers as neurotics, are notably absent in childhood. Many early stutterers when seen within the first year of their difficulty show no demonstrable deviation in the emotional sphere and present no history of environmental or psychological difficulties which seem at all adequate to explain the disorder. For this reason and since this volume deals largely with the developmental period of language, attention will be given here only to the phenomena of stuttering as they are seen in early childhood." "Many" stutterers show impediment as soon as they begin to talk. "Some delay" in beginning speech and in preferential handedness is common. It is "very common" to find an association with writing disability. The factor of inheritance is illustrated by nine brief family trees, showing various combinations of left-handedness, ambidexterity, stuttering, alexia, and agraphia. The emotional reactions and behavior patterns are discussed in ten pages. From the author's experience of "nearly a thousand cases of various types" he believes that the neurosis is the result, not the cause of speech difficulty. He "usually" obtained a history of "entirely normal development—physical, emotional and mental."

Orton's interpretation of the problem seems to boil down to this: inheritance plays a rôle in many cases of reading, writing and speech defects. Therefore the disorders are not entirely due to environmental and developmental factors, for inherited traits are due to structural differences in the genes. The cerebral hemispheres, although they appear alike anatomically, are unequal in their effectiveness, the left is usually dominant. The important process in speech development is the laying down of engrams. This is a physiological process taking place during the first eight years of life.

The last 43 pages of the book are devoted to treatment, and the methods used are described rather at length for alexia, agraphia and stuttering. Many stutterers turn out to have strephosymbolia and training is instituted to increase the superiority of the master hand. Phonetic training is given if there is imperfection of speech sounds. Reading is helped by pencil facilitation, *i. e.*, tracing the difficult initial letters as they come in reading aloud. The demand of oral responses is reduced to the minimum. The emotional factors must be carefully studied to prevent the development of personality disorders. In conclusion, Orton says: "The view here presented that many of the delays and defects in development of the language function may arise from a deviation in the process of establishing unilateral brain superiority in individual areas, while taking account of the hereditary facts, brings with it the conviction that such disorders should respond to specific training if we become sufficiently keen in our diagnosis and if we prove ourselves clever enough to devise the proper training methods to meet the needs of each particular case."

This work of Orton's deserves admiration. It has opened a whole field in child psychology. Nevertheless, several things in the book should not pass without criticism. The summary of aphasia is too condensed to be accurate and lacks references. The illustrations are crude and give an impression of final knowledge that is not in accordance with the often debatable facts. The original lectures were prepared for a medical audience, and it is to be deplored that in making them into a book, the author has attempted the impossible task of popularizing one of the most difficult chapters of neurology.

Orton's emphasis is on the importance of establishing normally a unilateral brain superiority. The evidence presented does not seem to the reviewer to justify such emphasis. The facts usually called psychological are given little consideration. The evidence for an inherited neural basis or a developmental physiological basis would be greatly strengthened if data were presented concerning these "nearly a thousand cases." One is left unconvinced when merely told certain traits are found "usually" or in "most cases." The scientist wants to see the evidence, and have concrete data. It means little to say that an "entirely normal" history of development was obtained unless one knows how much was investigated in how many cases. In fact *entirely normal* means (accurately speaking) *completely average*, and the reviewer doubts if any human history is just that. Important as the structural and physiological factors in the development of the language function must be in these children, and great though Orton's contribution certainly is, me-

thinks he doth protest too much against the psychological possibilities. The very fact that he considers that they "should respond to specific training" puts them into a category that most people would consider psychological. It reminds one of Pavlov's refusal to admit that there was any such thing as psychology!

Moreover, Orton leaves one hanging between the horns of a philosophical dilemma when he tries to distinguish between structural defect and physiological disorder. He says: "Since the normal pattern in the adult is a concentration of control of the functions under discussion in the hemisphere opposite to the master hand, and since our clinical observations show so wide a variation both in time and degree in the development of a selective preference for either side in many children, it is suggested that these disorders in language development may derive from a comparable variation affecting the essential language areas of the brain and thus rest on a basis largely physiological in nature and not dependent on defect or destruction of any part of the cortex."

Just what is the "comparable variation"? It apparently refers to lesions which cause aphasia in the adult by interfering with the function of speech centers in the brain. It seems to the reviewer that language and other symbolization is learned by a process of association, a high-level nervous activity of certain structural areas of the cerebral cortex. The inherited structure differs from person to person. During the laying down of the associations the many incidental, concomitant stimuli are probably important in conditioning the symbolization. Thus the intimate life history of each child while learning to speak is of great importance. Even if exactly similar lesions could occur in two different people the resulting speech defect would be different—in one the loss might be of German and in the other English, to take a simple example. The structural defect causes a disturbance of function that produces symptoms which vary widely according to the environmental conditions at the learning period. In other words, the problem is psychological, physiological, and anatomical. Trying to draw lines between these three is useless for the student of language development. The injuries that cause speech symptoms (be they pedagogical stupidities of apoplexy) cause a defect in the individual speech of that one person; they disrupt a psychologically determined pattern. The "developmental disorders" are, of necessity, psychological, even if the term carries with it bothersome connotations to neurological purists.

On page 155, Orton says, "We cannot at present accept the hereditary *transmission* of a purely functional character and believe that the passing on from the family stock of a strong preference for the use of the right or the left hand must rest on the transmission of a *better brain structure* in the left or right hemisphere, respectively, which in turn, leads to the development of a functional superiority." Certainly! But, one cannot accept the *existence* of a "purely functional character." It has to be a function *of* some structure or it would not exist. The book contains much that is interesting and im-

portant, but the lack of data is disappointing and the interpretations are neither clear nor convincing.

Harvard University.

LA MÉTHODE PSYCHANALYTIQUE ET LA DOCTRINE FREUDIENNE. Tome I, II. By *Roland Dalbiez*. (Paris: Desclée de Brouwer & Co., 1937.)

The title of these formidable two volumes succinctly reemphasizes the dichotomy—frequently overlooked—pervading psychoanalytic literature. The text stresses this basic differentiation obtaining between the exploratory method of free association and the exegetical elaborations of psychoanalytic doctrine.

In critique of method, Dalbiez professes his personal convictions of the extraordinary merits in free association, illustrating its revelatory prowess in several clinical case records; and little else.

There is no differentiation made between exploratory association and therapy. Discussion or comparison of the multiple means of harnessing the technique to render it productive is totally lacking. No mention is made of "activity," "passivity," "transference," and other pragmatic details, the abuse of which will liquidate, if not the method itself, then certainly its potency. The inexorable necessity of creating an intimate human affinity in the analytic situation escapes him, as does the realization that this human relationship between patient and analyst is the *sine qua non* of the therapeutic method.

From the case material cited by the author, it is evident that his thinking is allied to an early, ingenuous Freud, of the "cathartic" period, when psychoanalytic method was an alarm clock, which, once started, would spontaneously, after an appropriate lapse of time, ring out the pathetic bleating of an infantile traumatic episode, the patient then arising invigorated to plunge boldly into a new day.

At this late date then it is insufficient in a recondite text to give simple approbation to free association. Psychoanalytic method includes a therapeutic fraction with unique technique, procedure and implication, which must be delineated.

In exposition of the Freudian doctrine, divisible into psychology and philosophy, Dalbiez proves equally uncritical. Most informative is his orientation of Freud in the philosophic zodiac, indicating that his affiliation is with realism and empiricism. Dalbiez deems the former a valid ontologic position, demonstrating *en passant* the dialectic incompatibility between idealism and the unconscious. But epistomologically, as a militant rationalist and believer in "spiritual values," he categorically denounces the excursions of empirically grounded Freud into morality, art and religion.

Consistent with his philosophic adjudication, the author distinguishes between "superior" and "inferior" psychic processes. In the former is allocated reason, judgment and will; in the latter, emotions, affect and instinctual proclivities. The "superior" processes are alleged to be the more

"human"; and "L'oeuvre de Freud est l'analyse la plus profonde que l'histoire ait connue de ce que, dans l'homme, n'est pas le plus humain."

Although few individuals today will defend the Freudian theses in religion and aesthetics, any postulation of an intra-psychic hierarchy of value appears no more tenable. In somatic analogy, the heart is no more or less important than the brain. A man without an affect is by so much less a man. Affect can abet or undermine reason. The concept *man* comprises a totality of entities, relations and phenomena, any discussion of whose comparative value only descends into dialetic logomachy.

Yet what is certainly true is that Freud has never occupied himself with definitions of reason and judgment, confining himself to demonstration that an intellectual process is never pure and undefiled, but is inevitably and ubiquitously modified by "inferior" human processes.

Withal, Dalbiez apparently accepts unquestionably most of the basic Freudian dogma. No logical projectiles strafe the poorly fortified Freudian notions of "Anxiety," "Repetition Compulsion," "Narcissism," "Masculinity and Aggressivity," "Femininity and Passivity," "Oral, Anal and Urethral Erotism," "Œdipus Complex," "Fixation," "Instinctual Energies," etc.

He does question, however, the omnipresence of infantile sexuality and correctly prefers to consider children as "polymorphously pervertable," rather than as "perverse." In consequence, he labels adult sexual perversions as "paradifferentiations" and not as infantile fixations.

Dalbiez nurtures another characteristic typical of Freud. Both seek physiologic affirmation for the validity of psychologic tenets. Freud resorted to instincts; Dalbiez quotes Pavlov and overlooks that there is no parallelism but only interesting analogy between the behavior of a canine salivary gland and the behavior of man.

In fine, the two authors suffer a common defect in failing to detect the inexorable importance of sociologic considerations in the genesis of human activity. Both are unaware that psychopathies are strictly definable only in a given cultural setting and that sociologically ordained motives can be as significant as instincts in mobilizing human behavior.

With a newer knowledge available in anthropology and social psychology, a text, purporting to view psychoanalysis philosophically, which omits such contemplation, is certainly open to censure and reproach.

MEYER MASKIN, M. D.,
Bellevue Hospital, New York City.

MEDICINE AND MANKIND. By *Benjamin P. Watson, M. D., Howard W. Haggard, M. D., Harlow Brooks, M. D., George Draper, M. D., Foster Kennedy, M. D., Elmer V. McCollum, Ph. D.,* and *Alexis Carrel, M. D.* (New York and London: D. Appleton Century Co., 1936.)

Not all the currently circulating books avowing the purpose of assisting the layman to keep abreast of the progress of science can be set down, as good and useful books. The present volume however is one that serves its

purpose and offers delightful reading. It represents a group of lectures to the laity instituted by and delivered at the New York Academy of Medicine.

Dr. Benjamin P. Watson, Professor of Obstetrics and Gynæcology at Columbia University tells the story of the growth of knowledge of the anatomy and physiology of the human body, a narrative of romance and tragedy as well as scientific triumph. The reader is introduced to the great discoverers and the contribution of each is succinctly reported. We learn of Herophilus of the School of Alexandria, "the first real human anatomist," of Erasistratus, "the father of physiology," of Galen who learned much of his anatomy from treating wounded gladiators, of Vesaluis who dared to attack the Galenic tradition and became the founder of the modern science of anatomy.

It is of great interest to note how large a part renaissance are played in the development of the new science, especially the work of Leonardo da Vinci who, many commentators believe, profoundly influenced Vesalius.

Dr. Howard W. Haggard, Associate Professor of Applied Physiology at Yale University, contributes a chapter on medicine in the days of Louis XIV, an epoch which extended from 1643 to 1715. The illnesses of the monarch form the basis of this discussion, and since the royal contacts were with nearly all branches of the healing art his medical history affords a good index of the state of the science of his time. His first illness was small pox, contracted at the age of nine; next came a chronic venereal infection at 17; at 20 a fever probably typhoid; at 25 measles from which the King nearly died; then a long series of intestinal disturbances rightly or wrongly attributed to tapeworm (the author suspects indigestion from dietary indiscretions, associated with dental caries and pyorrhœa); at 47 a rectal fistula; and finally with the inroads of old age, gout, stones in the bladder, a gangrenous leg, arteriosclerosis. The grand monarch had need indeed of greater science than the medicine of his day could boast, but his pathology served at any rate some purpose. "Whatever may have been the benefit that Louis derived from medicine—and in some cases it was problematical, to say the least—there can be no doubt of the practical benefits conferred on medicine by the patronage of Louis."

Dr. Harlow Brooks, Emeritus Professor of Clinical Medicine at New York University, whose death occurred before the appearance of this book, writes on the contributions of the primitive American to Medicine. Pointing out that much of the medical lore of the early settlers was derived from the Indian medicine men, Dr. Brooks discusses the healing methods of the original inhabitants of this continent. They were skilled in the reductions of fractures and dislocations and in the treatment of wounds. The use of obstetric forceps and methods of dilating the cervix in delayed labor are reported, likewise the control of hemorrhage and even contraceptive measures. The Mayas performed amputations and made use of artificial limbs, and accomplished both cæsarian section and symphysiotomy in difficult labor. They practiced a kind of dentistry, including the fitting of false teeth.

Among the drugs in use by the Indians may be mentioned cocaine, and other hypnotics, cascara and saline laxatives, astringents, emetics and diuretics, quinine, salicylic acid (decoction of willow bark), digitalis.

Dr. Brooks rightly ascribes importance to ceremonial and ritual as an integral part of Indian medicine. From their clever use of suggestion the white man has something to learn. There is food for thought in the remark of an old Navajo medicine man: "You white men can treat some diseases a great deal better than we can, such things as gallstones and appendicitis, but I can treat some diseases much better than you can, such as diseases of the spirit."

As "the common denominator of disease" Dr. George Draper, Associate Professor of Clinical Medicine at Columbia University, develops the theme, adorned if not illuminated by some curious diagrams, of the individual otherness of each person as a factor in his tendency to illness. In some diseases the pathotropic tendency serves to act like a secondary sex character (gallstones and exophthalmic goiter more frequent among women; gastric ulcer more frequent among men). Draper mentions briefly some of the investigators who have contributed to the current concept of constitution, a composite of anatomical, physiological and psychological qualities with individual peculiarities of capacity and resistance which underlie the proneness to disease. This section partakes somewhat of the nature of a chalk talk.

The most original and stimulating chapter in this book is the discussion of the organic background of mind by Dr. Foster Kennedy, Professor of Neurology at Cornell University Medical College. By opposite examples he demonstrates how many aspects of what we call reason are determined and modified by bodily states, disturbances in endocrine function, focal lesions in basal structures of the brain. By understanding the evolutionary series of control levels in the central nervous system we likewise understand how the later acquired voluntary or rational facilities are the first to suffer under the influence of disease. Similarly by knowing that the visual faculty is made up of many parts which represent an evolutionary or developmental sequence, we grasp the fact that with a lesion in the angular gyrus these several qualities of vision tend to be lost in an order the reverse of that of their acquisition. The author refers to the behavior and mental states of patients suffering from encephalitis to show the organic basis of symptoms which cover nearly the whole range of psychopathology, what the individual human personality is depends upon the kind of teamwork his internal glands, his sympathetic nervous system and his midbrain are capable of.

The dramatic story of the vitamins and nutritional diseases is presented by Dr. Elmer V. McCollum, of the School of Hygiene and Public Health, Johns Hopkins University. Beginning with the experiment of Lunin (1881) by which he demonstrated that the four then known food constituents—proteins, carbohydrates, fats and mineral salts—if fed in purified form were insufficient to maintain health, McCollum sets forth the more important studies, practically confirmed within the past 25 years, through which the various specific health-maintaining constituents of food, called vitamins by Funk (1910), have been successively discovered, isolated, and in some cases

synthesized. Such nutritional diseases as beriberi, scurvy, rickets, ophthalmia, pellagra can now be dealt with effectively by appropriate dietary measures. Spectacular indeed have been the achievements of this young science of nutrition which permit the author to say: "The knowledge which we now possess concerning the nutritive needs of the body, and the properties of our more important natural and processed foods in terms of the known nutrient principles, is sufficient to enable us to cause malnutrition to disappear from the face of the earth."

In vivid antithesis to the theme of construction, maintenance and reconstruction in the story of the vitamins, stands the topic of the next and final chapter—the mystery of death, by Dr. Alexis Carrel of the Rockefeller Institute for Medical Research. Premature death, due to accident or disease, is, Carrel points out, the common one; natural death, the uncomplicated terminal event of old age, is exceptional. With the advance of medical science the number of premature deaths has progressively diminished and the average life span has been markedly extended. But insofar as social betterment is concerned, the fruits of science and the rise of humanitarianism do not constitute an unqualified blessing. "Death prevents the overcrowding of the earth. It liberates the new generations from the burden of the old. If the span of life were suddenly increased to 100 years, civilized countries could not stand the economic weight of populations composed mostly of senescent individuals. . . . . The success of our battle against death has almost suppressed natural selection. The weaklings have become artificially the equal of the strong. And civilized countries are encumbered with those who should be dead."

There is a period of apparent death following cessation of the heart action, during which resuscitation may be possible; but within a very few minutes (hardly six to eight—Crile) irreversible changes begin in the brain cells. Carrel therefore warns against efforts to resuscitate a patient belatedly. "For he might come back to life without his soul."

Carrel finds no scientific evidence to support the survival hypothesis, and the data of psychical research he finds quite unconvincing. "But no one has the right to say that such survival is impossible." He goes even further and asserts that it is not unreasonable "to believe that some part of human personality may escape death." In the same paragraph the author criticises the assumptions of the spiritists because they "neglect the fact of the existence of clairvoyance." It was necessary to go over this sentence again to make sure that it had not been misread; but there the words are in cold print—"the fact of the existence of clairvoyance." No supporting evidence is offered beyond the circumstance that mediums sometimes make startling revelations.

We have finished this compact volume which deals with varied aspects of life and health and sickness and death. The information is condensed but clearly presented, and most of the authors have said much in little space. Though designed for the laity, the student and physician will likewise find it refreshing and informing.

CLINICAL STUDIES OF DRUG ADDICTION, III.

A Critical Review of the Withdrawal Treatments with Method of Evaluating Abstinence Syndromes.*

By LAWRENCE KOLB,
Medical Director, U. S. Public Health Service,
AND
C. K. HIMMELSBACH,
Passed Assistant Surgeon, U. S. Public Health Service.
U. S. Public Health Service Hospital, Lexington, Ky.

Addiction to opium, as expressed by physical dependence upon the drug and tolerance to large doses of it, is a self-limited condition that quickly disappears regardless of and in spite of what treatment is given to cure it, provided the drug is taken away from the patient; but addicts are notoriously subject to relapse, especially in a country which, like the United States, so efficiently regulates the opium traffic that comparatively few persons with normal nervous constitutions become addicted to it or remain addicted for long periods. The old unstable addicts come back for treatment time after time and this doubtless has lent weight to the idea that the addict has suffered some physical damage or change due to opium that makes his return to the use of it inevitable unless the damage can be remedied and the supposed physical craving obliterated by some form of physical therapy.

The relapse of cured drug addicts is due not only to physical dependence but to original psychic stresses, relief from which produces the seductive calm that leads in most cases to the use of opiates to the point of physical addiction; and to memory associations and habit that are built up by the practice over long periods of time of relieving mental and physical distress and pain by the use of opiates. The evaluation of these factors and the relative importance of them have been discussed in another paper.[1] It is sufficient here to state that the physical factor is of minor importance except in some cases of addiction that have lasted for years.

* Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

Withdrawal of the opium is all that is necessary in nervously normal addicts and it is very simple to take the drug from them, but it is clear that withdrawal therapy is the most unimportant phase in the treatment of emotionally-unstable drug addicts. Such patients must be rehabilitated mentally and emotionally if permanent cure is to be effected. We are, however, not concerned in this article with the means by which this rehabilitation is brought about.

Withdrawal therapy has attracted a great deal more attention and much is still being written about it. New treatments said to be specific are advanced from time to time and then discarded as useless or even harmful, or old treatments are revamped and presented as new. Endocrinology, immunology, and chemistry have been invoked to explain the ultimate nature of addiction and prove the virtue of certain lines of treatment. All of this, together with the fact that the treatment of physical addiction is so easy and yet so difficult and discouraging when the patient cannot be controlled, has tended to becloud the issue.

We shall not review all the literature on the subject but refer the reader to Terry and Pellens [2] for a bibliography on withdrawal therapy and extracts of the more important articles written about it up to 1928.

Treatment falls into types. Our object is to discuss the more important types and to present a method of selecting patients for research and of evaluating withdrawal symptoms that experience has shown will guard in the future against errors that have caused the acceptance of useless and even harmful treatments in the past.

Two common sources of error have contributed to the improper evaluation of methods of treatment. First, addicts with the same degree of physical habit react to the discomfort of withdrawal with widely different degrees of mental intensity. Temperamental, neurotic or cringing individuals complain bitterly of symptoms that normal persons and many psychopaths who have made up their minds to go through with the treatment, come what may, do not complain of at all. Much is made of restlessness, nervousness, pain and fear of impending collapse by patients who show none or very little of such objective manifestations as vomiting, diarrhea, tremor and insomnia; while others showing these and other objective symptoms to an intense degree may complain very little and say they are doing quite well. Second, most addicts who come in for

treatment today do not have strong habits because they have been getting an inadequate supply of adulterated drug at irregular intervals or have been deprived of their favorite drug for several days and are, therefore, almost over the withdrawal period when they are received for treatment. If investigators would take account only of objective symptoms; eliminate from studies all subjects with weak habits; use controls, and remember that with few exceptions all addicts from whom they take the drug will quickly get over the physical withdrawal symptoms regardless of what other treatment they are subjected to, fewer errors would be made.

Treatments fall into three main groups: slow withdrawal, rapid withdrawal and abrupt withdrawal. A number of specific treatments have been grafted upon the rapid and abrupt withdrawal methods. The slow withdrawal method was in almost universal use up until about 45 years ago. By this method the daily dose of opiate is gradually reduced over a period of a month or more,* using various techniques not essentially different from one another. It was the method of choice in homes and a modified form of it is still used with success in some sanitaria. After the rapid withdrawal method (withdrawal in from a few days to two weeks) was introduced much of the writing was concerned with the relative merits of it and slow withdrawal. The issue seems to have been settled against slow withdrawal, not because treatment by this method is impossible, for with proper cooperation and favorable environment the withdrawal if slow enough can be accomplished with so few symptoms that the patient is hardly aware that the opiate is being withdrawn, but because it is seldom necessary and is, as a rule, impractical. If the patient can be controlled, slow withdrawal is not necessary; if he cannot be controlled, he is likely to change his mind and discontinue treatment before it is finished, or use the treatment for several weeks merely to get opiates. Sincere

* This is purely arbitrary. Writers on drug addiction vary as to the time element of slow and rapid withdrawal. In order to avoid uncertainty as to what is meant we classify as rapid any withdrawal in two weeks or less, and as slow any withdrawal in one month or more, and consider any time between two weeks and one month as intermediate; this may be either rapid or slow depending on the severity of the habit. This intermediate period is usually regarded as slow.

addicts, who are temperamental or subject to unusual variation in moods, change their minds about the desirability of cure when slight discomfort or an attack of blues comes on. Insincere addicts start the treatment to fool their doctor or to make insistent relatives or friends believe they are sincere.

BELLADONNA TREATMENTS.

The belladonna group of drugs has been widely used in the treatment of opium addiction, and some form of belladonna treatment dominated the situation for a period of about 30 years beginning in 1901. Treatment by these drugs is absolutely useless and even harmful to addicts in withdrawal, but because so much has been written about it and articles continue to appear [3] in which such treatment is lauded, a brief review of the use of these drugs will be given. Their wide and continued use illustrates the errors that may creep into observations as to the efficacy of treatments and supports our own observation that addicts often get over the withdrawal period in spite of, rather than because of, what is done for them.

Lott [4] in 1901 first brought the hyoscine treatment forcibly to the attention of the medical profession, although drugs of the belladonna group had been used before in the treatment of addiction, but not in such a drastic manner as that employed by Lott. Petty [5] in the same year brought forth his hyoscine treatment and later on claimed the dubious honor of having been the first to introduce it.

With the patient still under the influence of morphine, Lott began his treatment by giving 1/100 grain of hyoscine hydrobromate and continued with 1/200 grain at 30-minute or 1-hour intervals for from 24 to 48 hours; the object being to produce "hyoscine intoxication." According to Lott, the patients have diarrhea but do not suffer during this period. Nevertheless, he states that they may see and imagine things that do not exist, and grow "quite wild," and he recommends that they be taken care of in a downstairs room by a strong nurse constantly at the bedside so as to prevent self-injury or injury from falls, as the patients are "incoordinate and unable to stand." Lott gave only up to three 1/4-grain doses of morphine during this period and sometimes found it necessary to give strychnine, nitroglycerine or digitalis for the heart. He states that at the end of the first delirious period the patient "no longer craves the drug and would not take it."

The second stage is then begun with the administration of 1/8 grain of pilocarpine every hour until the physiological effect is produced. Sufficient of this drug is given to maintain the effect until "the drugs that have been stored in the cord and body are eliminated." During this period and afterwards his patients suffer with diarrhea, yawning, sneezing, pains, cramps, restlessness and insomnia for which various remedies are given. After a week or 10 days appetite returns but pains, nervousness, restlessness and insomnia continue and are controlled by hot and cold baths, bromides, chloral, massage with liniments, pilocarpine, atropine, hyoscine, strychnine and electricity.

Lott offered no theory of drug addiction but the inference is gained that he thought morphine was stored in the cord and other tissues and should be eliminated in order to effect a cure. Lott's patients certainly suffered more according to his own description than patients who receive abrupt withdrawals without any drug treatment.

It is mainly due to Petty [6] that the belladonna treatment came into almost universal use in this country. Petty based his treatment on the theory that the essential pathology of addiction "is intoxication of drug, intestinal and auto-origin," and he claimed that most of the symptoms incident to the withdrawal of drugs are due to these toxins. He stated further that "at least six of the most troublesome and dangerous complicating symptoms incident to the abrupt withdrawal of opiates have their origin in . . . . deficient excretion. These are intestinal colic, nausea, vomiting, diarrhea, labored and deficient heart action and collapse." Acting on his toxemia theory he laid great stress on aiding elimination as an essential of treatment, especially elimination by the bowels. He thought that purgatives and secretory stimulants were not sufficient, in fact, they made conditions worse by causing the pouring out of secretion in the upper bowels, so "benumbed by morphine" that the secretions would not move on. According to him, nausea, vomiting, deficient heart action and collapse were caused by these secretions and an engorged portal circulation. In order to overcome this condition he used what he considered a physiologically balanced purgative compound to overcome the semi-paralyzed bowel function. The key to the Petty treatment is purgation and scopolamine and the essential of his purgation is strychnine—to stimulate

peristalsis in the "paralyzed bowels." Of this drug he gave in many cases 1/8 grain every two hours until four doses were given and he has given as much as 1/4 grain every two hours until one grain was given in eight hours. This was in addition to the strychnine in his purgative compound.

Petty took his patients off morphine in from 30 to 36 hours. He started his treatment with an elaborate system of purgation and began the administration of scopolamine about the time the morphine was discontinued. He did not make his patients wildly delirious, as did Lott, but kept them under a mild "belladonna intoxication" for from 36 to 48 hours. He continued to give purgatives during the delirious period, at the end of which, according to him, his patients began to have small bilious stools that fully cleansed the system of toxic matter. This occurred by the end of the fifth or sixth day from the beginning of treatment. Petty found it necessary, as did Lott, to give sparteine sulphate to support the heart during the active treatment or convalescence. Petty placed greater stress on the purgation which he thought overcame the toxins that are the "principal cause of suffering in these cases" than he did on the scopolamine, but he said for hyoscine (scopolamine) that it "not only occupies but fills, when properly used, as important a place in the treatment of morphinism as does chloroform or ether in the practice of surgery." According to him, it relieves pain, prevents undue nervous strain and exhaustion, arouses certain nerve centers which the opiate has blunted and produces a secondary "stimulation of the secretory and excreting organs."

A variant of the hyoscine treatment that was extensively used in this country for 25 years is one introduced by Lambert and often referred to as the Towns-Lambert Treatment.[7] It is a rapid withdrawal method in which heroic purgation and a "specific" consisting of a mixture of 2 parts of tincture of belladonna and 1 part each of fluidextract of xanthoxylum and fluidextract of hyoscyamus is given by mouth. Lambert states that this treatment brings about a real obliteration of the craving for narcotics and that under the influence of the specific the patients do not suffer from the intense diarrhea that usually accompanies the withdrawal of morphine but that energetic, drastic, cathartic medication is necessary to obtain the desired elimination. Lambert only aims to bring about a mild belladonna intoxication by the use of his specific and according to

him in from two to three days after the treatment has started his patients have a liquid green stool following a dose of castor-oil after which they often feel suddenly relaxed and comfortable.

Lambert has varied his treatment somewhat from time to time [8-10] and, depending upon indications, has used in addition to the purgatives and specific other drugs such as oxgall, phenacetin, caffeine, pyramidon, salicylates, sodium nitrate, sodium bromide, sodium bicarbonate, codeine and chloral.

Lambert's treatment was less drastic than either the Lott or Petty treatments and in his hands doubtless benefited some patients especially in view of the fact that he treated them symptomatically and used sodium bromide, sodium bicarbonate and codeine—three drugs that do have some effect in alleviating the severity of withdrawal symptoms. The belladonna specific is, however, in our experience definitely harmful and it is of interest to note that Lambert himself has changed his mind about the usefulness of the belladonna group of drugs.[11]

There are many varieties of treatment besides those given in which some member of the belladonna group of drugs is used because of its supposed specific action. Scott [12] states that "the morphinist is one who has been accustomed to preserve vagal predominance and sympathetic depression by means of his drug" and that during withdrawal "atropine secures for him the steady vagal tone which means a smooth passage to recovery." He withdrew the morphine slowly while giving small doses of atropine and administered luminal in large and increasing doses. Goods results were reported.

It is apparently true that in withdrawal there is a tremendous stimulation of sympathetic functions but the action of morphine and atropine on the vagus and sympathetic system is so complicated that the total picture of withdrawal and the action of atropine cannot be encompassed in such a simple theory. Atropine depresses the parasympathetic system and one might logically conclude from this that such depression would still further augment sympathetic predominance during withdrawal and thus make conditions worse. In any event, theory must give way to clinical observations which definitely show that this group of drugs increases the suffering of patients. The Mayor's Committee on Drug Addiction,[11] by using controls, eliminated any doubt about it.

Our own observations confirm the findings of the Mayor's committee and one may well wonder why drugs so definitely harmful to addicts during withdrawal should be considered beneficial. The "knock-out" feature of these treatments, especially Lott's and Petty's, doubtless had the effect of holding until cured many patients who would have discontinued a withdrawal treatment before being cured, and the psychological effect of doing something for patients practically all the time has a tendency, by allaying apprehension, to hold them even though what is done is harmful.

The theories advanced for the use of the belladonna group of drugs and of purgation, pilocarpine and strychnine are unsound. It is true that small doses of morphine and hyoscine antidote each other, but in morphine withdrawal we are not laboring to antidote the physiological effect of morphine but of abstinence from it. Lott gave morphine to his patients when they showed evidence of serious hyoscine poisoning, but we may ask why give a patient who is seriously ill a poison that needs to be counteracted by another poison?

As to the use of pilocarpine, all secretions of patients in withdrawal are increased because of the withdrawal and this is largely responsible for the vomiting and diarrhea as well as the sweating. A drug that increases these secretions as pilocarpine does can, therefore, only add to the distress of the patient. One reason given for the use of purgatives and pilocarpine in withdrawal treatment is that they increase the elimination of morphine. If this is true, it is a good reason for not giving them, because the organism is suffering at this time because of abstinence from, not the presence of, morphine in the body.

Treatment by strychnine, as advocated by Petty and others, is just as illogical as treatment by purgatives and pilocarpine. The patient in withdrawal is hypersensitive, restless and apprehensive, and strychnine, by increasing the acuteness of perception, aggravates these symptoms. Its use in withdrawal illustrates again that patients from whom morphine is taken get well in spite of the treatment.

The fundamental change in the human organism that brings about addiction is not known, but one thing is certain—it is not due to auto- or intestinal-intoxication, nor are the symptoms of withdrawal due to either one of these toxemias. Extreme purgation is, there-

fore, illogical. The only effect of such purgation is to devitalize the patient and increase the danger of collapse and death.

Deaths Under Treatment.

Most writers on drug addiction speak of the danger of death from withdrawal, but in a fairly comprehensive though incomplete review of the literature we find reference to only eight * actual cases.[13-16] Unreported deaths must be fairly common as we have knowledge of 11 cases. Six of these occurred in one year in a hospital where 130 patients were given the hyoscine treatment. Two received a modified Towns-Lambert treatment in which the specific and purgation were given without any morphine, it being considered in the hospital where they were treated to be more or less sinful and criminal to give morphine to an addict. One was a woman about 60 years old with a strong habit who was given abrupt withdrawal because it was thought somehow to be morally wrong to give morphine to an addict even in treatment. One, a man 62 years of age, died under abrupt withdrawal. (Information was not definite as to whether this man collapsed in a heat cabinet.) One, a man 42 years old, with a possible but unproved heart lesion, suddenly collapsed under abrupt withdrawal. Hyoscine, belladonna and purgatives undoubtedly increased the distress of eight of these patients and contributed to their deaths.

Peptization and Water Balance Treatments.

Bancroft, *et al.*[17] have proposed a theory of drug addiction and a treatment based upon it. According to them, the protein colloids of the nervous system are coagulated (agglomerated) by the morphine in chronic morphinism and these colloids may be dispersed again by a peptizing agent, the best of which, according to them, is sodium thiocyanate (sodium rhodanate). They do not use the words "peptization" and "coagulation" in the ordinary sense but state that "in the case of the nervous tissue we are probably dealing with jellies and the whole thing may well be a question of more or less

* Since writing the above, there have come to our attention three additional cases reported by Piker and Gelperin in Ann. of Int. Med. 10 (O. S., XV), 1279, 1937, and one by Obersteiner in Internat. klin. Rundschau, 1891, 5, 1840-1843; abstracted in Centralbl. f. klin. Med., 1892, 13, 524.

bound water, the former is equivalent to peptization and the latter to agglomeration" (coagulation). They state that when morphine is taken up to a certain point it is "adsorbed by the protein colloids of the nervous system causing reversible agglomeration or its equivalent, the loss of bound water. . . . . Upon withdrawal morphine leaves the tissues slowly and peptization takes place gradually, or the equivalent, more water is bound, giving rise to excitement which is manifested by withdrawal symptoms," and "in the course of time the peptizing agents normally present in the body return the nervous systems to their correct degree of disperson and the patient recovers."

Bancroft lists a number of other drugs besides morphine that are agglomerating agents and in a review of treatments of drug addiction he notes that many of these have been used and states that they are worse than useless, as they tend to aggravate an already agglomerated condition of the nervous tissues. According to him, the only treatments reviewed by him that have merit from the point of view of his theory are those that employ sodium bicarbonate, sodium bromide, ephedrine (peptizing agents) or withdrawal without drugs. Bancroft also applies his theory of the agglomeration and peptization of nervous tissue in an explanation of certain mental diseases.[18] His theory as to drug addiction may contain a clue as to the ultimate nature of it, but his experiments do not prove it. We shall not discuss the theory, however, except the practical application of it to the treatment of drug addiction by the use of sodium rhodanate.

From a perusal of the clinical histories of his cases we are forced to the conclusion that if he had used controls he would have found that those receiving sodium rhodanate suffered more than the controls. In one article [17] he cites at considerable length in support of his theory four cases treated by sodium rhodanate. Two of these cases had been taking only four grains of morphine daily for two and six years, respectively, and both of them became wildly delirious and psychotic during withdrawal under sodium rhodanate, although the morphine was not abruptly withdrawn. In one, the psychosis lasted 16 days and in the other approximately two months. Bancroft thinks that one of these patients had on admission a psychosis that was masked by the use of morphine. This case was obviously inferior, but an important point in the clinical history is that a

psychosis that was not observed on admission and became very striking under sodium rhodanate, cleared up after the sodium rhodanate was discontinued. The patient was discharged in better condition mentally than on admission.

In our experience with hundreds of cases we have not had one become psychotic during the withdrawal period but one of us has encountered two cases of 30-year addiction in which the patients became mildly hypomanic after withdrawal.[1] The development of psychosis during withdrawal is, therefore, a possibility, but nothing seems to be more unlikely than the development of two cases out of four in persons who had recently become addicts.

Bancroft does not consider the delirium and psychoses produced in his patients of any importance, but it is of interest that he quotes Borg [19] to the effect that under potassium thiocyanate four patients suffering with high blood pressure developed a toxic psychosis that lasted from five to seven days after the drug was stopped. Bancroft, however, warns against the use of potassium thiocyanate, but Borg [19] also reports psychoses produced by the sodium salt.

In addition to the psychoses, Bancroft's two patients suffered with all the usual symptoms of withdrawal including elevation of temperature, elevation of basal metabolic rate, restlessness, profuse sweating, vomiting, pains, etc., and one of them had involuntary bowel movements, a symptom which we have never observed in other forms of treatment. One of the other two cases in his series of four refused to take sodium rhodanate after the fifth day, presumably because it upset his stomach, a symptom of which all of them complained.

The remaining case, No. 1 in the series, is the only one of the four that was not made distinctly worse by the treatment. The morphine was withdrawn from this one in six days and the sodium rhodanate continued for some time afterwards. According to the description this patient had symptoms at least as severe as 50 per cent of present-day addicts who receive abrupt withdrawal, the only difference being that as treated the symptoms were more prolonged.

We have not used the sodium thiocyanate treatment for drug addicts, but Dr. Marion R. King of the U. S. Public Health Service [20] tried the drug on 10 patients and discontinued it because it invariably produced gastric discomfort accompanied by nausea and

vomiting and made no favorable impression whatever on the withdrawal symptoms. It was a common occurrence for his patients to vomit two minutes after swallowing a capsule. It is only fair to state here that King did not use recrystallized sodium rhodanate in order to insure purity as recommended by Bancroft.

Bancroft's mistaken conclusions about the value of sodium thiocyanate in the treatment of drug addicts are apparently due to unfamiliarity with the clinical picture during withdrawal. He says,[21] "The withdrawal symptoms met with upon attempting to cure drug addicts by withholding the morphine are very much like those described by Borg [19] upon prolonged administration of large amounts of sodium thiocyanate for the relief of hypertension: disorientation, hallucinations of sight and hearing, mania, confusion and ideas of persecution, singly or in combination. These symptoms are not due to the same cause because the sodium thiocyanate overpeptizes the brain colloids of the normal person." Such symptoms do not occur during the withdrawal period except when patients are given delirium-producing drugs.

Bancroft and Rutzler [21] have definitely shown that sodium thiocyanate antagonizes morphine. This doubtless explains in part why the drug is harmful during the withdrawal period as the patient is then suffering because of abstinence from morphine and he needs morphine or some similarly acting agent to reduce the severity of the symptoms.

Inadequate information as to the clinical picture during withdrawal and the effect of certain drugs upon it has caused praise of some rather remarkable treatments. Church,[14] using Macleod's "bromide sleep" treatment (120 grains sodium bromide every two hours), revived by the use of oxygen, strychnine, etc., one patient who had been brought near death by the treatment. This patient lost 18½ pounds in weight in 20 days. In our experience the average patient loses about 6 pounds during the withdrawal period and regains it by the twentieth day. Another patient who received the treatment died and Church reports two deaths out of ten patients treated by Macleod. He recognizes the danger of this form of treatment but was so favorably impressed by it that he advocated its use in well-selected cases.

Bromides in small doses do relieve to a certain extent the restlessness and insomnia from which all addicts suffer during with-

drawal, but given to the point of delirium they definitely retard recovery and are dangerous.

Adler,[22] working on Barbour's hypothesis [23] that abstinence manifestations are the result of tissue hydration, treated a number of addicts with various diuretics. She reported particularly favorable results with euphylline. We have been unable to confirm any objective value from this type of therapy. The clinical picture and blood studies have consistently indicated that anhydremia is associated with the abstinence period.

Lipoid Treatments.

The fact that opium is supposed to act upon the nervous tissues and that these tissues contain lipoids has been used by some observers to construct theories of drug addiction and treatments based upon these theories. The most widely heralded of these treatments and also the most useless and harmful is the narcosan treatment. The author of this treatment [24] states that "It is a well-established fact that the lipoids of various organs as well as of the nervous system may be extracted and consumed by the administration of narcotic alkaloids" and that the "lack of sufficient lipoids in the nervous system is responsible for the longing for drugs." He further states that "We are in a position to determine synergy of various lipoids which enables us to replace the lost lipoids of the body up to a normal point, bringing the patient into a normal condition both physically and mentally."

A treatment was invented which was said to be a solution of lipoids together with non-specific proteins and water-soluble vitamins and it was claimed that patients taking this treatment "will soon become normal and develop a contempt for the opiates which is most pronounced." [25]

Lambert and Tilney,[13] reporting on 366 cases treated by narcosan, confirmed this observation with the statement that "this substance was self-protecting against the patients indulging in narcotics on the sly." They were very favorably impressed by the narcosan treatment and stated in explanation of its action "that narcotics, such as morphine, call forth in the body certain protective substances to neutralize them. If the narcotics be suddenly withdrawn, and not given, these neutralizing substances are themselves toxic to the

body. The lipoids in narcosan neutralize these toxic substances in place of the narcotic."

Scheib,[26] reporting on 1700 cases including the 366 treated by Lambert, was so impressed that he reported results "unparalleled by any other known treatment"; while Johnson,[27] comparing the results of 24 narcosan treatments with 12 cases treated by other methods, found no benefit. The treatment excited a great deal of interest and was finally studied by the Mayor's Committee on Drug Addiction.[11] This committee, by the use of controls, found that the narcosan treatment was not only not beneficial, but it increased all the distressing symptoms of withdrawal and was positively dangerous to life. The report of this committee is of especial interest because Lambert, who had previously reported favorably on the narcosan treatment, was chairman of it. The history of the narcosan treatment illustrates very well the errors that may be made by uncontrolled observations of addicts during the withdrawal period.

Other lipoid treatments have been presented,[28] notable among them is one based on a theory advanced by Ma. Ma [29] states that the amount of lipoid material in the body cells of opium addicts is reduced almost to nil in serious addiction and when lecithin is administered orally lipoid material is gradually increased, while the craving for opium correspondingly subsides. He advances the hypothesis that by continuously administering lecithin an automatic disappearance of the opium habit and a subsequent reduction of opium tolerance might be expected. He claims experimental proof of this hypothesis.

In support of his theory that the lipoids are depleted in chronic morphinism, Ma [30] found quantitative changes in the Golgi lipoids, alterations in the nucleus and slight changes in the mitochondria in the cells of morphinized rats. MacEwen and Buchanan,[31] repeating Ma's work but using dogs, demonstrated by means of controls that there was no significant variation from the normal in any of their morphinized animals.

In 1932 Ma [32] made a lecithin feeding experiment on a group of 143 opium smokers and was favorably impressed but stated that further experimentation was necessary. In 1935 a more favorable report was issued.[29] The patients subjected to this experiment were allowed to have all the opium they wanted to smoke in the customary

manner but were required to take from 20 to 30 grams of soya-bean lecithin by mouth three times a day, after meals. It is stated that the patients receiving this treatment show a less and less desire for opium and eventually take no more of it, the time for effecting a cure varying from 4 to 22 days.

We have not experimented with this treatment but we do not feel that the experimental evidence upon which it is based is sound. There is no conclusive evidence proving that the lipoids of nervous tissue are depleted by narcotics and even if they are it is not logical to assume that the mere feeding or injection of lipoids would remedy the deficiency, especially while the narcotic is still being administered.

Endocrine Treatments.

A supposed disturbance of endocrine function due to addiction has been referred to by several authors. Some of the symptoms that the patients show during tolerance suggests that the thyroid function may be inhibited and the anxiety, general restlessness and increased metabolic rate that ensue upon withdrawal suggest thyroid overactivity. Likewise, the fact that during withdrawal the blood sugar level is always raised indicates an overactivity of the adrenals, but it is not known whether these glands are directly affected by withdrawal of morphine or whether the effect comes through a disturbance of nervous control. The sympathetic system is obviously stimulated during withdrawal and this could act as a stimulant of the adrenals with a consequent outpouring of epinephrin or the stimulation of adrenal secretion could come indirectly from an over-active thyroid gland.

The endocrine treatment that has excited most attention is that advanced by Sakel [33-35] who believes that withdrawal symptoms are caused by oversaturation of the nerves with epinephrin and a disturbance in the equilibrium of the vegetative nervous system. Insulin, according to him, eliminates signs of abstinence by re-establishing the equilibrium and he attempts to counteract the withdrawal symptoms by the use of this drug and sedatives. He begins the use of insulin as soon as withdrawal symptoms set in and administers it for from six to eight days in doses up to 80 units in 24 hours. Along with this he gives small quantities of ergot of rye and choline in order to equalize a disturbed balance in the para-sympathetic-

sympathetic system during the acute withdrawal period. He at first gave glucose with the insulin but later on discontinued it and controlled hypoglycemic manifestations by regulating the insulin dosage.

Sakel does not attempt to bring about insulin shock in morphine withdrawal and his theory of the action of insulin in this condition differs somewhat from his theory of its action in schizophrenia.[36] In the latter disease he is on somewhat more solid ground in so far as the accuracy of clinical observations is concerned.

A weak point in his theory in relation to morphine withdrawal and the effects of insulin upon it is that while epinephrin has many effects, insulin has only one—namely, the burning of carbohydrates.

Other observers treating a small number of patients with insulin [37-43] have reported favorable results, but a few have not been impressed. None used controls.

Sakel states that his patients under the insulin treatment began to gain weight in seven days. Our patients, under any form of treatment, including the controls who get no drug medication whatsoever, begin on the average to gain weight four days after the last dose of morphine.

It is extremely difficult to evaluate the effect of treatments in an explosive condition like morphine withdrawal that subsides in a few days regardless of what treatment is given for it. The only way to be sure of the action of a given remedy is to give it only to strong cases of addiction without drug medication and use controls or give the controls the same supplementary medication. Intravenous glucose or sedatives in moderation or both have been used by the various observers along with the insulin. These measures in our hands are effective without insulin. By excluding from the research cases with mild habits (80 per cent of the total) and taking account of all factors, we found that insulin had no effect on withdrawal symptoms. Insulin, of course, brings the blood sugar down but there is no reason to believe that the high blood sugar incident to withdrawal is of itself the cause of any of the symptoms. This, together with some other withdrawal phenomena, is in all probability due to an overactive sympathetic system from which an artificial check has been suddenly removed. However this may be, experience with treatments thus far has shown that time alone restores the apparently stimulated sympathetic to normal.

The ovarian hormone has also been used with reported favorable results in the treatment of drug addiction. This treatment was apparently suggested by the fact that this hormone has a chemical structure somewhat similar to that of morphine. Pettersson [44] used ovarian panhormone on two cases and thought the results justified a further trial of this remedy. He also gave pernocton, veronal, luminal and paraldehyde with the hormone. His patients suffered with restlessness, insomnia, diarrhea and distressing pains in the legs such as might be expected on the withdrawal of opium from addicts with mild habits. We have not used this treatment but are inclined to believe that the evidence so far presented about it is not encouraging.

Immunity Treatments.

Hirschlaff,[45] Geoffredi [46] and others have attempted to explain tolerance and the withdrawal symptoms along the lines of Erhlich's theory of immunity, the general idea being that morphine acts as an antigen for the production of antibodies which are poisonous and cause abstinence symptoms when the morphine is withdrawn. Pellini and Greenfield [47] and DuMez and Kolb [48] failed to find anything in the blood of addicts that increased tolerance to morphine or produced symptoms similar to the abstinence symptoms of the donor, and there is no conclusive evidence that alkaloids cause the formation of antibodies as do protein derivatives. Nevertheless, treatments which have this theory as a background have been invented and reported upon favorably.

The most important of these is Modinos' autogenous serum therapy.[49] Modinos found that blister fluid contained hydrocarbons, lipoids, oxydases, lipases and a high leucocyte count (20,000 to 80,000), and he thought it contained antibodies that had therapeutic value against withdrawal symptoms. He thought that these antibodies were more numerous in the blisters than in the blood because of an excess formation of antibodies between the layers of the skin. Acting on this theory he produced an artificial blister and after 12 to 14 hours withdrew serum from this blister and injected it under the skin in amounts of from 5 to 20 cc. Two other injections were made at intervals of four days while the opiate was gradually withdrawn. Modinos claimed that withdrawal symptoms were slight and that the patients so treated have no desire to return to the drug.

Reddish,[50] Huizenga [51] and others [52] have reported favorably on this treatment while Noordhoek Hegt [53] was not favorably impressed. Huizenga injected from 1 to 5 cc of serum each time. Two of his 10 patients refused morphine after the second injection. All of them quickly gained in weight and all of them were free from craving in from six to 14 days. Huizenga's conclusions are not convincing in view of the fact that practically all patients, regardless of the type of treatment, begin to gain weight on the fourth day after the last dose of morphine, and practically all are free of physical craving after from six to 14 days. Biggam [43] treated some of Modinos' patients who had relapsed. He tried the blister treatment on 40 cases, using controls who were treated at the same time by the application of blisters and injections, not of serum, but of a normal saline. The only effect that Biggam noticed from the blister treatment was that the blister caused considerable discomfort. The two groups showed no difference in withdrawal symptoms but both of them had considerable discomfort from the blisters.

Otterloo and Bonebakker [54] employed a method similar to Biggam's and got the same results. They point out the fallacy of Modinos' antibody theory but think that the blister treatment has suggestive value by drawing the patient's attention away from himself to the painful blister through which he is led to believe that the condition from which he is suffering is extracted. Commenting on the claim that patients treated by the blister method become sensitive to opium and are made sick by it, they correctly state that it is the usual thing for opium users to become indisposed after the first dose. The blister treatment does not differ in this respect from any other treatment.

The virtue of the Modinos treatment is supposed to lie in the antibodies contained in the serum of the blisters, but the treatment embodies probably the best treatment known for mild cases of addiction, namely, a rapid withdrawal of the opium which is given is small doses for a period of five or six days. Substitution of this treatment for definitely harmful treatments has doubtless led in some cases to erroneous conclusions as to the value of the blister serum that would not have been made if a series of controls had been treated by the reduction method without the blister.

While employing a five-day "sleep method" in which the patients were kept in a semi-sleep condition through the administra-

tion of luminal and certain hypnotics, sedatives and analgesics, Kwa and Tan [15] lost two patients out of fifty treated by them. One attendant was required for every two patients treated by this method in order to watch for signs of collapse and prevent them from injuring themselves in their "half awake" state. Even this was not successful as they often "woke up with cuts and bruises." Naturally, their opium smokers who apparently had very light habits did much better under a reduction treatment lasting from three to six days even when they were subjected to a blister or two.

C. S. Mei, Director of the Chapei Anti-Opium Hospital, Shanghai, has administered the blister treatment to over 5000 patients. He states [55] that the treatment has only a psychological value, and apparently he gives it because he feels that the patients' minds must be set at ease by giving them the idea that something tangible is being done for them. We have found this psychological factor to be very important in the treatment of drug addicts. Any form of treatment, even though it increases the severity of the objective symptoms as so many treatments do, gives them a subjective sense of relief through allaying the fear so many of them have that nothing will be done for them. Intensely apprehensive patients complain bitterly about any type of withdrawal if it is started as soon as they enter the hospital, while the same type of patients, if stabilized on morphine for a few days until they get used to the environment and find that some interest is being taken in them, may then be taken off the drug without exhibition of fear and without showing undue subjective phenomena. We have not found it necessary, however, to subject a suffering patient to the added discomfort of several blisters in order to ease his mind.

Autohaemotherapy (injection of blood previously drawn from the patient) is another treatment based upon the theory of immunity that has been reported upon favorably. Biggam [43] tried this treatment on 152 patients and found that it had no effect on withdrawal symptoms nor did it have any tendency to prevent patients from relapsing, as had been claimed by certain observers. In this treatment blood was obtained from a superficial vein and injected deep in a muscle usually in the gluteal region. Injections of from 2 to 60 cc were made daily for about seven days.

A theory [56] of morphinism advanced along with a remedy (rossium) is given by Ostromislenski. This theory makes use of im-

munity and anaphylaxis and is referred to by the author as the "Anaphylactic Theory of Morphinism." The treatment has been reported upon favorably by Raynor and Bauer,[57] and by Lambert.[58]

Ostromislenski quotes Bishop's Theory of Morphinism to the effect that " under the action of morphine, the organism of man and animals produces a special substance, an antidote " which in the free state possesses " the properties of a strong poison " and the severe symptoms of morphine withdrawal are due to the action of this substance. However, in the systems of addicts this antidote reacts with morphine becoming quite harmless and at the same time rendering the morphine harmless. He says that Bishop's theory takes care of all the facts except one, namely, that a subcutaneous injection or ingestion by mouth of a quite insignificant dose of morphine (a mere 0.0001 gram) is sufficient to produce a relapse of the disease. Ostromislenski further states[59] that " this insignificant dose may produce relapse even when complete abstinence has continued for a number of years " and the patient " has no idea that morphine has been introduced into his organism," and " if the ex-addict does not resume daily injection of the opiates he will inevitably undergo within a few days, all the severe withdrawal symptoms which he experienced during his previous treatment." [60]

Ostromislenski thinks that the withdrawal symptoms of morphinism are due to anaphylactic shock. The mechanism described by him is as follows—morphine produces antigen, the antigen produces antibodies which in the absence of morphine unite with antigen and produce shock. In support of his anaphylactic theory he states that an individual who takes morphine daily will not need morphine to prevent withdrawal symptoms until the twentieth day; in other words, addiction begins suddenly about this time. The appearance of sensitization at a definite time would fit in with the observed facts in anaphylaxis produced by an injection of protein substances.

Ostromislenski's theory is built upon three errors—namely, that the withdrawal symptoms are similar to the symptoms of anaphylactic shock; that addiction begins suddenly at a definite time; and that a minute dose of morphine given to a former addict will bring on addiction with all the withdrawal symptoms. As to the symptoms, there is nothing in morphine withdrawal that compares with the edema, urticaria, choking sensation, cyanosis, cough and difficult

breathing characteristic of anaphylactic shock in guinea pigs, nor are the symptoms comparable to those of serum accidents in man. The symptoms of anaphylactic shock are produced by the injection of a substance to which the organism is sensitive, while the symptoms of morphine withdrawal are produced by withholding the morphine and are relieved by injections of it. Addiction does not start suddenly on the twentieth day as claimed. Both clinical experience and animal experimentation show that it develops gradually. The statement that a minute dose of morphine given to a former addict will bring on addiction with all the withdrawal symptoms would, if true, be an important point in favor of the anaphylactic theory. We have shown that it is not true by giving morphine to hundreds of former addicts without in one case bringing on craving or withdrawal symptoms. However, the fact that Ostromislenski's theory is erroneous does not of itself disprove his claims about rossium.

No conclusions as to the value of rossium can be drawn from Raynor and Bauer's cases as these cases all received insulin, a reported specific for drug addiction, together with sodium amytal, intravenous glucose and codeine. Assuming, as we do, that insulin is useless, we attribute what slight favorable effect these authors observed to the intravenous glucose and codeine as we have found that both of these remedies decrease the severity of withdrawal symptoms.

In order to determine the value of rossium, Himmelsbach [61] treated four groups of patients as follows: First, abrupt withdrawal without any drug medication; second, the rossium treatment as given by Raynor and Bauer omitting the codeine and substituting ipral for the sodium amytal; third, the adjuncts to the rossium treatment as given by Raynor and Bauer omitting the codeine as well as the rossium and substituting ipral for the sodium amytal; fourth, rossium alone without any drug medication. These four groups showed exactly the same objective manifestations of withdrawal both in degree and kind, but the two groups receiving intravenous glucose had a subjective feeling of relief from some of the discomforts for about two hours after the glucose was given. The conclusion was that rossium had no value in the treatment of drug addiction.

PSYCHOTHERAPEUTIC TREATMENTS.

A conditioned reflex treatment [62] has been reported upon as giving favorable results in ameliorating the abstinence symptoms of morphine withdrawal. Only a few cases were treated by this method and the report is not convincing especially in view of the fact that the morphine was not abruptly withdrawn from the patients who were said to be conditioned. There is no reason to suppose that these severe, temporary, self-righting, organically-conditioned symptoms should be favorably influenced to an appreciable degree by psychotherapy.

Hypnotism has been tried and one author,[63] using it more with the idea of bringing about permanent cure than of relieving the severity of withdrawal symptoms, is so favorably impressed that he would force all relapsing addicts to submit to hypnotic suggestion in order that they might acquire a repulsion for drugs. He had under observation for from 9 to 35 days patients who received such treatment from him.

Two cases previously shown to be easily influenced by hypnotic suggestion with proved strong habits were treated by Dr. Victor H. Vogel, a member of the staff of the Lexington hospital.

The first case was put into a deep trance one hour after the last dose of morphine. About 12 hours later he began to mumble and groan and show other signs of restlessness but he remained asleep 11 hours longer and then awoke perspiring and complaining of back and stomach pains. He was rehypnotized and awoke again in a few minutes and it was found impossible after that to keep him asleep. Suggestions had been given to him that he would not suffer but he subsequently had the usual objective signs of withdrawal and complained a great deal although he thought that he slept better than during previous treatments.

A deep trance was induced in the second case one hour after the last injection of morphine but he awoke in 30 minutes frightened and complaining of a dead feeling in his hands and legs. He was reassured and put to sleep two more times with the same results after which the attempt to carry him through his withdrawal period by hypnosis was abandoned.

Dr. Vogel was not favorably impressed by this treatment. According to him, even if it reduces to some extent the severity of

withdrawal symptoms, it is likely to be of limited value as it requires the constant presence of the hypnotist and extremely suggestible patients.

Abrupt and Rapid Withdrawal Treatments.

The abrupt withdrawal treatment has been extensively used in prisons in recent years. It was, however, advocated by some observors as being the treatment of choice as long as 50 years ago. An advantage of the treatment is that the suffering is quickly over and the patient rapidly returns to normal. It is, however, not without danger, especially in old or debilitated persons or persons with diseased hearts. Some of the specific treatments use abrupt withdrawal, or withdrawal in from 24 to 36 hours, which amounts to practically the same thing, and the fact that the patients as a rule survive in spite of the added burden put upon them by the drugs that are given (hyoscine, narcosan) indicates that this treatment can be safely used if these drugs are omitted and care is exercised in the selection of patients for it.

Many addicts who present themselves for treatment at the present time have weak habits or are already partly cured. This condition has prevailed for a number of years and is growing more evident as time goes on because it is becoming increasingly difficult to secure undiluted drugs illegally and physicians are growing more and more reluctant to furnish narcotics to addicts even when they might consider the cases to be worthy. We find, as a result of this state of affairs, that only about 20 per cent of addicts have sufficiently strong habits when they come in for treatment to justify their inclusion in a research program designed to test the efficacy of cures. These weak habit cases do well under abrupt withdrawal combined with certain supportive measures—sedatives in moderation, baths, etc., and perhaps an occasional dose of codeine for two or three days. This, we believe, is the treatment of choice for such patients provided the heart is in good condition. For addicts with strong habits abrupt withdrawal is cruel, dangerous and unnecessary. Such treatment is often given in prisons and sometimes in hospitals because of a feeling that the addict does not deserve anything better. This, of course, goes along with a generally hostile attitude towards the addict that is bad psychologically and lays the ground work for relapse.

The Mayor's Committee on Drug Addiction [11] found that patients suffered less under rapid withdrawal than under any other form of treatment tried by them. In a seven-day withdrawal the patients, after being stabilized on morphine had one-seventh of this amount withdrawn each day for seven days; in a fourteen-day withdrawal the patients, after being stabilized, had one-fourteenth of the amount withdrawn each day; in a codeine-morphine withdrawal the morphine was rapidly withdrawn in four days while codeine was given in five-grain doses three times daily, alternating with injections of morphine. On the fifth day five-grain doses of codeine were given every four hours and the dose gradually decreased until on the seventh and last day of the treatment a total of only six grains was given. There was less suffering under the seven-day codeine-morphine withdrawal than under the morphine alone, and still less under the fourteen-day morphine withdrawal. It was found, however, that a prolongation of the treatment caused some trouble because the suffering, though less intense, was more prolonged.

The method of choice in our experience is a rapid withdrawal except for those patients who have weak habits and come in partially cured because they have already been deprived of the drug for several days. A few doses of codeine given to such patients over a period of two or three days, is all that is necessary and it is surprising how little they suffer.

Many patients are extremely apprehensive of treatment. They expect to suffer more than they actually do and some of them fear death. It is, therefore, desirable to stabilize all patients with strong habits and some of those with weak ones on a few grains of morphine a day, usually not more than four, until they get used to the environment and grow to feel that they are not going to be treated with brutal indifference as so many of them have been treated before. It is surprising how such patients calm down under this preliminary treatment and go through the withdrawal period, even if it is abrupt, without fear and often without complaint. After the patients have been stabilized we withdraw them, depending upon the indications, in from four to ten days using codeine or morphine or both drugs in small doses. It is desirable to give enough to take the edge off the suffering and prevent collapse and we believe as to the latter that no healthy person who receives as

much as three grains of morphine in small doses between the 24th and 96th hour of the withdrawal period will die from the withdrawal regardless of the length of habit or amount of drugs he has been taking, provided he is not given toxic doses of other drugs or subjected to debilitating physical therapy.

Along with the withdrawal the patients are given as many as three ten-minute warm baths during the day. We find that these baths decrease the restlessness. Patients who do not eat well are given 1,000 cc of five per cent intravenous glucose as often as three times per day. These infusions reduce the weight loss, probably by maintaining water balance, and also give a subjective sense of relief from the restlessness for about two hours. Diarrhea is controlled by five grains of bismuth subcarbonate three times daily when necessary. If at the beginning of treatment the patient is constipated an enema is given. Extensive purgation is never used. The Mayor's Committee [11] treated patients by the use of hypnotics, sedatives and analgesics and found that none of them gave any obvious advantage over abrupt withdrawal, and some made the patients worse. This is doubtless true in the main when patients are given large doses of these drugs, but an occasional dose of any of them, especially at night, will be beneficial by promoting sleep. We prefer paraldehyde for this, giving from 12 to 20 cc in olive-oil by rectum. We have also found that sodium bromide given in from 15 to 45-grain doses three times daily with 30-grain doses of sodium bicarbonate for four or five days reduces the restlessness of the patient without producing any harmful effects. We carefully watch patients receiving bromides so that the drug can be discontinued if evidence of toxicity appears.

Comment.

We have shown that all treatments based on theories of the mechanism of drug addiction have been failures. The mechanism remains obscure and we have no theory about it but offer the following as a partial explanation, not of the mechanism but of some of the withdrawal phenomena that depend upon the disorganization of it: the functions of the sympathetic nervous system are depressed by morphine. In chronic users there is a reaction against this depression that tends to restore the functions to normal. This functional reaction increases as the dose of morphine is increased

(increased tolerance). When the morphine is withdrawn the reactive mechanism designed to counteract poisonous doses of it continues to work for some time. This causes powerful stimulation of certain functions under the control of the sympathetic—hence, the sweating, goose-flesh, increased secretions causing vomiting and diarrhea, increased blood sugar from increased outpouring of adrenalin, raised blood pressure, etc. The fact that this reactive phenomenon is peculiar to addiction to opiates argues for the condition of dependence rather than mere tolerance. There is also an apparent thyroid overactivity due to overaction of a previously depressed thyroid. But removal of the check from the sympathetic and thyroid obviously does not explain the whole picture. The entire central nervous system apparently reacts in the same way as the sympathetic; therefore, in withdrawal, more intense perceptions are received by centers that are more sensitive to them. Hence, the insomnia, pain, restlessness, anxiety, etc. The universality of the reaction in the nervous system probably explains why drugs specifically acting upon one part of it are not generally beneficial.

It has been shown that many serious investigators and clinicians have made errors in clinical observations of withdrawal symptoms of opium addiction due mostly to the fact that they have not taken into account the numerous variable factors that enter into the study of any series of cases. As a result of these errors useless and even harmful treatments to control or mitigate the severity of the symptoms have been widely used. In order that such errors may be avoided in the future we have studied under controlled conditions in a group of addicts the abstinence syndrome with the purpose of increasing our knowledge of the phenomena of deprivation and of providing an impersonal, purely quantitative method of abstinence evaluation which would give accurate estimates of the daily intensities of abstinence and yet be sufficiently simple to permit of wide usage in the clinical testing of withdrawal therapy.

To insure uniformity in withdrawal phenomena we consider it important that patients used to evaluate treatments should have not only proved strong habits but that before being withdrawn they should be stabilized within a certain close range as to daily dosage. The patients forming this study were stabliized on from 240 to 340 mgs. of morphine per day.

Methods of Study of the Abstinence Syndrome.

Sixty-five addicts were studied during the last week of satisfied dependence and the first ten days following abrupt withdrawal. The presence of pre-established strong dependence was demonstrated in all these cases prior to the initiation of study. All of these patients were studied under the same experimental conditions. Thirty-five of these cases received medication following withdrawal which has been shown in no way to affect the objective abstinence phenomena. This group consists, therefore, of 65 addicts with proved dependence from whom narcotics were abruptly withheld and who subsequently exhibited characteristic deprivation phenomena which were not perceptibly modified in intensity or extent by any of the therapeutic measures administered at this time.

For the purpose of elucidating and measuring the abstinence syndrome, data were obtained daily during the last week of addiction and the first 10 days of abstinence on the following accurately measurable signs: Rectal temperature, respiratory rate, blood pressure, basal metabolic rate, blood sugar, caloric intake, weight, and sleep. Measures of rectal temperature and respiratory rate were made three times daily. Blood pressure determinations were made at the same time each morning before breakfast with the patient in the supine position. Basal metabolic rate determinations were made on patients in the post-absorptive state after 45 minutes of observed rest in bed. Blood sugar determinations were made on samples of venous blood drawn at the same time each morning before breakfast. Caloric intake was estimated by obtaining the weight of all foods consumed (amount served less the remainder) and the use of standard tables giving the caloric values of various foods. Weight, stripped, was determined at the same time each morning on a " silk scale " accurate to 10 gm. Sleep was estimated by observations made at half-hourly intervals throughout the entire period of study. Observations for the presence of the non-accurately measurable signs of abstinence were made three times daily throughout the entire period of study.

The data obtained were subjected to the following statistical treatment for the purpose of determining the significance of abstinence deviations from addiction levels. Addiction means were determined for each of the accurately measurable signs in every case. The *group* addiction means are the means of the *case* addic-

tion means. The group addiction means were then compared with the group means for each day of addiction and abstinence through the use of critical ratios. Critical ratios of three or more are considered to indicate statistically significant differences. The complete data are presented in Tables * I to X. The daily abstinence means were plotted graphically by using the respective addiction means, except for weight, as the ordinate base lines. Abstinence weight deviations were plotted from the last day of addiction because of the consistent gain in body weight during the stabilization period. These graphs, presented in Fig. 1, show the direction and extent of the daily abstinence deviations, and whether the differences between the addiction and daily abstinence means are statistically significant. These graphs were prepared in such a manner that the maximum deviations, in each measure, are of about the same ordinate extent. The abscissae intervals indicate days following withdrawal, and are equal in all graphs.

A Quantitative Method for Estimating Objective Abstinence Syndrome Intensity.

The desirability of a simple, impersonal, quantitative method for estimating the intensity of the composite abstinence syndrome has been discussed in a previous report.[61] It is felt that the method to be described meets these requirements satisfactorily, since its scope is sufficiently broad to include the prominent effects of withdrawal, and since the measures involved are limited to common hospital procedures. The use of this method requires adherence to a program best suited to this type of investigation. The program outlined below is felt to meet the research requirements of the withdrawal treatment problem, and to be adaptable to most institutions:

1. Hospitalization and segregation of the patients to be studied are necessary in order to control all of the factors which might influence the study. Prevention of the introduction of narcotics is essential.

2. Demonstration of the presence of definite physical dependence in all patients on whom withdrawal treatment studies are to be made is essential to the validity of the studies. This is accomplished by withholding narcotics

* The complete data in Tables II to X are not given here. A composite result of these tables showing the means, standard deviation, standard error, standard error of the difference and the critical ratio are given. The complete tables will be furnished by the authors upon request.

until the deprivation phenomena set in and reach a marked intensity. Most patients will understand that it is necessary to establish a diagnosis before instituting treatment and will submit to a 24 to 30-hour period of abstinence for diagnostic purposes.

3. A stabilization period of at least one week prior to the withdrawal of all narcotics and the beginning of the treatment to be evaluated is desirable. During this time the dependence requirement is met by the administration of the minimum amount of morphine, or one of its derivatives, necessary to prevent appearance of objective evidence of abstinence. It has been found that equal doses of morphine administered subcutaneously at 6 a. m., 11 a. m., 5 p. m. and 10 p. m. satisfy dependence satisfactorily no matter what drug, route, or interval the patient had been accustomed to prior to admission. The actual requirement is usually much less than the patient thinks, but must be ascertained by trial.

4. Narcotics should be withdrawn abruptly and the last dose should be given at the same hour in all cases. In this study, the last doses were always given at 10 p. m. It is not advisable to start withdrawal of many cases at the same time. We believe that it is better to start the withdrawals separately at not less than two-day intervals, since this facilitates more thorough observation and treatment of the individual case, and affords the others the opportunity to observe for themselves that the abstinence syndrome is not so severe as they had imagined.

5. Control cases receiving no treatment should be studied at regular intervals.

6. The presence or absence of the following non-accurately measurable signs of abstinence, to a significant extent, should be recorded three times daily throughout the entire period of study:

Yawning.	Anorexia.*	Goose-flesh.
Lacrimation.	Dilated pupils.	Restlessness.
Rhinorrhea.	Tremor.	Emesis.
Perspiration.		

Formal examinations for these signs should be made three times daily at 6 a. m., 2 p. m. and 7 p. m. Rectal temperature and respiratory rate should be measured at the same times. Blood pressure (supine position), and weight (stripped) should be measured at the 6 a. m. observation.

7. From the accurately-measurable and non-accurately measurable signs the daily intensity of abstinence is determined in the following manner:

Abstinence fever, hyperpnoea, and elevation of systolic blood pressure are scored on increases over their respective addiction means. Temperature and respiratory rate values for each day are the averages of the three daily determinations. Weight loss is measured from the last day of addiction. The

*Anorexia may be scored either when the total caloric intake for a day is 40 per cent less than the addiction mean, or as a *poor* appetite when appetite is estimated as good, fair, poor, or none.

following numerical values have been assigned to the signs of abstinence observed and measured:

The scores for accurately measurable signs of abstinence are as follows:

Fever: 1 point for each 0.1° C. (rectal) rise.

Hyperpnœa: 1 point for each respiration per minute increase.

Systolic B/P: 1 point for each 2 mm. Hg. rise (up to 30 mm.).

Weight: 1 point for each pound loss (or 2.2 points for each Kgm.).

The scores for the non-accurately measurable signs of abstinence are as follows:

Yawning, Lacrimation, Rhinorrhea, Perspiration ..... 1 point only for any of these signs observed on any one day.

Anorexia, Goose-flesh, Dilated pupils, Tremor ..... 3 points only for any of these signs observed on any one day.

Restlessness ..... 5 points only in one day.

Emesis ..... 5 points for each emesis observed.

The score for any 24-hour day is the sum of these points.

Results and Discussion of Quantitative Method.

The composite intensity of the abstinence syndrome exhibited by the 65 cases studied has been scored by both the quantitative method outlined above and by the method of estimated degree described in previous reports.[64-66] Comparisons of these methods are made in Table I and in Fig. 1 (intensity of abstinence syndrome). It will be seen that the quantitative point method corresponds quite closely to the method of estimated degree through the fifth day of abstinence, and that it shows recovery to be slower thereafter.

Following withdrawal significant changes (Fig. 1 and Tables * II to X) in caloric intake, blood sugar, rectal temperature, respiratory rate, blood pressure, basal metabolic rate, and sleep took place. Changes in blood sugar and caloric intake were not statistically significant after the fourth and sixth days of abstinence, respectively. Changes in body weight were not statistically significant. The rest of the measures studied showed significant changes through the tenth day of abstinence.

* See note on page 786.

Following the abrupt withdrawal of morphine and its addictive derivatives from addicts who have acquired physical dependence there occurs a very characteristic group of signs and symptoms

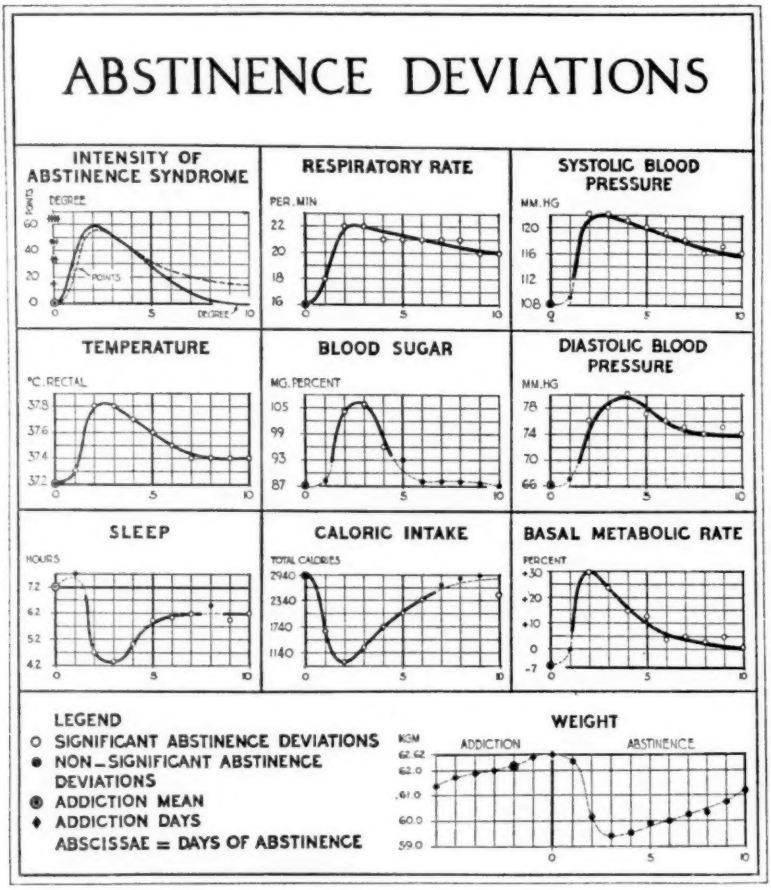

FIG. 1.

which have been termed the " abstinence syndrome." Many of the signs of abstinence represent measurable deviations from addiction levels. The addiction levels are within normal limits, but may or may not represent the individual normal levels. Most of the measurable abstinence deviations are statistically significant for at least

10 days after withdrawal. Whether this indicates the assumption of new levels or incomplete physical recovery cannot be determined by this study, but we believe that recovery is not complete in 10 days.

The change in body weight which takes place following withdrawal would seem to be statistically non-significant since the critical ratios are all below three. The reason for this is felt to be that body weight is the only one of the measures studied which showed wide individual variation, and hence gave relatively large standard deviations. All of the cases lost weight following withdrawal.

Summary and Conclusions.

Types of treatments of the abstinence syndrome of opiate addiction are presented and discussed.

No adequate theory of the ultimate nature of opiate addiction has been presented and treatments based on theories have been failures.

Tolerance to opium and physical dependence upon it are self-limited and quickly disappear when the opium is withdrawn regardless of what treatment is given for it.

Sudden or too rapid withdrawal may cause death but unwise treatments have contributed to most withdrawal deaths.

The treatment of choice for patients with strong habits, based on present knowledge, is rapid withdrawal, in 14 days or less, supplemented by certain supportive measures.

Patients with mild habits respond very well to abrupt withdrawal, together with a few small doses of codeine and supportive measures.

About 80 per cent of addicts of the present day have such mild habits that they are unsuitable for testing the value of treatments.

The intensity of withdrawal symptoms varies in addicts with the same degree of tolerance.

Only objective symptoms of abstinence are valuable in measuring the intensity of the symptoms.

A quantitative system for measuring abstinence is presented based on accurately-measurable and non-accurately measurable objective signs.

DISCUSSION.

DR. WALTER BROMBERG (New York).—I wish to congratulate the authors of this paper on their entrance into a field where the hope of therapy often outruns the achievements, and to congratulate them on the critical attitude which they have taken in this difficult field.

Our experience at the Psychiatric Clinic at the Court of General Sessions does not include the treatment of addicts. Treatment is carried out in the city prison where the rapid withdrawal method is used, and we see the individuals after they have been cured, prior to their sentence and we have opportunity to study their personality, our chief function in this particular group.

I was struck in reading the manuscript of Dr. Kolb's and Dr. Himmelsbach's paper on their noting the psychological effect of treatments of various kinds. I have often been struck by the recurrence of drug addicts in individuals who go to penintentiaries after their release. Many of our repeaters tell us that within six hours of their release from the penitentiary, they are back in the habit; some wait a few days or a month longer. Perhaps part of this is due to the conception of a socialist attitude on the part of physicians, penitentiary wardens, and so forth, in the treatment of drug addicts. The drug addict feels socially rejected, and perhaps rightly, the drug addict is looked upon as an evidence of social deterioration. The prisoner, then, is able to expatiate his guilt by receiving this severe treatment. He feels, having been punished by society, both in the way of social attitudes about drug addiction and in the technique of the drastic treatment, that he is able to go forth and resume his habit. Too little is known about the psychology of drug addiction as far as I have been able to find out.

The types of cases we deal with are those of the lower strata of society, but one knows little about the reactions in the offender himself from contact with drastic types of treatment.

The very interesting and important point in the author's paper which Dr. Kolb did not bring out is that of bringing quantitative standards to the measurement and valuation of subjective data. Physicians are in the habit

of judging treatments and the success of treatments by their objective findings and by subjective impressions which patients or offenders give them.

As I read the original charts and saw the data on which these graphs were based, I was able to see an important point of departure which the Doctor has brought out. They use this statistical method which rules out the probabilities of contingency between several factors. They, for example, plotted out the chance relationship of things like increase in weight or decrease in weight, increase or decrease of sugar in the blood, and so forth. In this way, there is a check on the rather large amount of credulity which all physicians must acknowledge in the judgment of success of any given type of treatment.

This attempt to check clinical judgment by the success of treatment is important, particularly in the field in which I am interested, namely, psychiatric criminology, because we have not only the subjective attitude of the physician, but the subjective attitudes of society which impinge on the physician as a member of society, and the judgment of the subjective attitudes of offenders, particularly of drug offenders, so that I find the statistical method of estimating chance occurrences of symptoms and deviations from chance occurrences are of particular value and importance in this type of work.

It seems that this opens a relatively new field in the adoption of methodology accepted in other branches of endeavor, such as sociology and psychology in the evaluation of psychiatric data and treatments. It opens a field of empirical clinical investigation which deserves careful scrutiny and attention.

DR. ROBERT S. CARROLL (Asheville, N. C.).—I presume I am the only one present who knew Dr. Lott, of Cameron, Texas, to whom Dr. Kolb referred today. I happened to be living within sixteen miles of him at the time he read his paper in June, 1901, outlining the use of hyoscine, or hyoscine hydrobromate, and within a few months the problem of morphine addiction was thrown upon my shoulders in an institution. Here the old extension and reduction method was employed. After I had seen one or two cases so treated, I was reminded of cutting off a cat's tail a quarter of an inch every day or two. That didn't seem quite the humane thing to do, so we utilized Dr. Lott's method, with this theory: It is not a specific; we are giving the patient an anesthetic during a period of deprivation symptoms, and the patient doesn't need large doses, not nearly the dose that Dr. Lott prescribed.

We soon learned if the patient could be kept in a state of twilight sleep, or forgetfulness, while the deprivation symptoms were going on, or during that period, all was well and good, and the deprivation symptoms—I might speak rather emphatically of my belief that there is a toxic condition which is relieved by castor oil, and for many, many years, in private institution work we have been very successful.

I am quite in agreement with the Doctor, that it isn't the removal of the drug that is the problem at all, that is very simple. Stop the drug, give scopolamin, give an ounce of castor oil every morning, and you will not have any vomiting, you will have no diarrhea, you will have no sweating. If they

begin to vomit, give more castor oil. Two ounces a day isn't any too much if the diarrhea gets bad. You have very little diarrhea with enough castor oil. You have something that may be called diarrhea, but it is quite different.

The real problem is the readjustment of the defective individual to society, and for that reason we receive no drug patients in our institution for less than a four-month period, of which ten days is used to eliminate the drug, and three months and a half to trying to teach that man how to live without the drug.

DR. LAWRENCE KOLB (Lexington, Ky.).—I wish to thank Dr. Bromberg and Dr. Carroll for their remarks, especially Dr. Bromberg for bringing out our statistical method, which I did not have time to talk about in reading the paper.

There was one other thing which is important, and that is the rossium treatment. This treatment has been advertised a great deal. It is based on the so-called anaphylactic theory of drug addiction, which is erroneous. We have tried the treatment in the Lexington Hospital, using controls, and we found rossium in the treatment of drug addicts to be absolutely useless.

CIRCUMSCRIBED CORTICAL ATROPHY IN THE PRESENILE PSYCHOSES—PICK'S DISEASE.

A Clinicopathologic Study.*

By CHARLES DAVISON, M. D., New York City.

Circumscribed cortical atrophy (Pick's disease), a form of presenile psychosis, is a rare disease and so far only two clinicopathologic studies have been reported in the English literature (Ferraro and Jervis,[1] and Lowenberg [2]). The disease occurs in individuals between the ages of 45 and 60 and is usually characterized clinically by progressive intellectual deterioration, focal symptoms such as aphasia, apraxia, agnosia, alexia and other neurologic signs depending upon the extent of the lesion. Pathologically, there is atrophy of the frontal and temporal and less often of the parietal convolutions. At times, all the convolutions of one hemisphere may be atrophied. The gyri are shrunken and narrow and the fissures are widely separated. The outstanding histopathologic picture consists of involvement of the gray matter of the atrophied convolutions. The nerve cells of the various lamellæ, especially those of the first, second and third layers, are decreased in number and show chromatolytic and chronic cell changes. This form of circumscribed cortical atrophy must be differentiated from Alzheimer's disease and senile dementia.

Report of Cases.

Case 1.†—E. N., a man, aged 63, painter by trade, admitted to the Elgin State Hospital, Elgin, Ill., June 24, 1932. The family history, except for a brother who died of hypertension at 70, was negative. The patient completed the eighth grade of school. His health had always been good until the age of 20, when he had pneumonia and typhoid fever. At times he complained of "painter's colic." He had no other serious illnesses or operations.

---

* From the Neuropathological Laboratory and the Neurological Division of the Montefiore Hospital, New York City. Read at the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

† I am indebted to Dr. Charles F. Read and Dr. I. Finkelman for the report of this case.

He worked for the Pullman Company as a painter until 1929. He smoked excessively, but never used alcoholic beverages or drugs. He had been married twice. His first wife died and the second wife left him when his memory began to fail. There were no children or miscarriages from either marriage.

In 1929 the patient worried a great deal because he lost his job. At this time his memory became impaired and he was unable to recognize his sisters. Although he recognized faces, he could not remember names. He could not follow a conversation, seemingly because he was unable to keep his mind on any subject for any length of time. Shortly before admission to the institution, he complained of vague pains in the lower abdomen. During his stay there he slept much during the day but little at night.

Mental Examination.—The patient was restless, constantly moved about in his chair, and touched the wall, table, and his face with his hands. He seemed distractible, starting at every sound. At times he appeared despondent but this expression easily changed to a silly, childish smile and he seemed happy. He was confused. When shown a watch, he could not tell the time or give its name. He fondled the watch and seemed pleased with it like a child with a new toy. To most of the questions he answered, "I do not know how to talk." He denied having any sisters or brothers. He was very uncooperative and was disoriented for time and place. He repeatedly asked for his clothes and said, "You make me feel bad. I'm in a bad shape."

Physical and Neurological Examination.—An emaciated male, 5 feet, 7 inches tall, weighing 112 pounds, who continuously held his hands tightly to his scrotum. Heart and lungs were negative; blood pressure was 160/90; pulse rate, 60. The teeth were in poor condition but did not show any lead lines. The right pupil was irregular but reacted to light and in accommodation; there was a cataract of the left lens. Hearing was impaired bilaterally. The deep reflexes were slightly hyperactive. The abdominal reflexes were present but the cremasteric reflexes could not be elicited. There were no other pathological reflexes. A careful sensory status could not be done because of the lack of cooperation.

Laboratory Data.—The urine disclosed a specific gravity of 1.006, a slight trace of albumin, many leukocytes, and a moderate number of red blood cells. The Wassermann and Kahn tests of the blood and spinal fluid were negative. The cerebrospinal fluid was negative; the colloidal Lange reaction was 0011100000.

Course.—The patient had loss of sphincter control and became weak. He shouted, "I don't know how to talk," and his stream of speech consisted mostly of "Don't bother me." He behaved peculiarly. He moved the chair up against the wall after patting the chair and then the wall. He touched all objects within reach. He assumed many postures and was very distractible. He was unstable emotionally and showed an oscillation of mood. He mumbled to himself and his responses indicated confusion, disorientation and loss of memory. There developed ulcers and edema of both ankles. He died from lobar pneumonia March 24, 1934.

Autopsy.—Gross Examination: There was a lobar pneumonic process of both lungs. The heart was normal. The aorta contained calcified atheromatous plaques with some ulcerations. The bladder was small and contracted; the mucosa was somewhat injected and finely trabeculated. The prostate was small but normal. The prostatic urethra and verumontanum showed atrophy. All the other organs were normal.

Brain: The brain weighed 1075 grams. There was slight atrophy of the left frontal, first, second and third right temporal convolutions and marked atrophy of the first, second and third left temporal convolutions and of the fusiform and hippocampal gyri (Fig. 1). The convolutional atrophy was best seen upon the removal of the meninges. The brain was cut coronally. The right hippocampus appeared more atrophic than the right temporal convolutions. The caudate nuclei were slightly shrunken. The left insular convolutions were also atrophied. The convolutions in the region of the left posterior horn appeared normal. The brain-stem and cerebellum showed no abnormalities.

Microscopic Examination.—Brain: Coronal sections of the left and right hemispheres were cut separately and stained with the myelin sheath and cresyl violet methods. Additional stains with the following methods: Holzer, Bielschowsky, Sudan III, Braunmühl, and Hortega stain for microglia and oligodendroglia, were made on other sections from various parts of the entire central nervous system.

Sections of the left hemisphere, through the basal ganglia, disclosed a wide separation of the fissures, atrophy of the frontal convolutions, and marked atrophy of the temporal convolutions (Fig. 2A). The white matter of the second left frontal convolution contained a few lacunæ; the white matter of the left temporal convolutions, especially on the inner surface, was partially demyelinated. The cortical gray of the temporal convolutions at this level was separated from the white matter. The right temporal convolutions also appeared slightly atrophic (Fig. 2B) and their white matter stained poorly.

In sections through the thalamic nuclei, there was marked atrophy of the first two left temporal convolutions and of part of the fusiform and hippocampal gyri (Fig. 3A). The gray matter of the third left temporal convolution was slightly separated from the white. The right temporal convolutions were also slightly atrophied (Fig. 3B). In sections further caudally, the outstanding atrophy was in the third left temporal convolution and in the hippocampus. In sections through the posterior horns, there was slight atrophy of the superior parietal and inferior parietal convolutions. In the complete coronal sections stained with cresyl violet, the cortical gray of the affected convolutions took a slightly deeper stain.

Small sections were taken from the various cortical convolutions.

First, second and third left frontal convolutions: The arrangement of the cyto-architectural layers was slightly distorted; this was best observed in the third frontal convolution. Most of the ganglion cells stained poorly; they contained little cytoplasm and, in many, the nuclei were displaced to the periphery. Some of the ganglion cells were slightly disintegrated. Dropping-

out of ganglion cells was most marked in the second and third frontal convolutions, while more marked chromatolytic changes were seen in the third left frontal convolution (Fig. 5). The changes in the ganglion cells were equally distributed throughout all the cortical layers, especially in the upper layers. There was a slight increase in the glial elements. The cortical vessels showed moderate atherosclerotic changes. No abnormalities were noted in the white matter. In the Sudan III preparation, deposits of fat were noted in the ganglion and glia cells. Proliferation and hypertrophy of astrocytes and microglia cells were best observed in the silver preparation. The right frontal convolutions showed insignificant pathological changes.

Left temporal convolution: The entire cortex at this level was thinned out. There was distortion in the arrangement of the cyto-architectural layers, and increase in the glia cells, most noticeable in the last three layers (Fig. 4). The ganglion cells, especially those in the last three layers, were slightly swollen, chromatolytic (retrograde changes) and contained peripherally displaced nuclei. Complete destruction of some of the ganglion cells in the third and fifth layers was also noted. Some of the blood vessels and capillaries showed atherosclerotic and hyalin changes with areas of degeneration around them. Collections of amyloid bodies surrounded some of the perivascular spaces (Fig. 6). Occasional hypertrophied microglia cells were noted. In some areas a slight amount of free blood pigment or pigment engulfed in compound granular corpuscles was seen. In the Holzer preparation, there was astrocytic proliferation in both the gray and white matter and marked gliosis of the white matter (Fig. 7). In the Sudan III preparation, small amounts of fatty deposits were found in the perivascular spaces. The ganglion cells of the third and fifth layers were loaded with fat. Senile plaques or Alzheimer ganglion cells could not be demonstrated in the Braunmühl or Bielschowsky preparations.

Slight pathologic changes were also noted in the right temporal convolutions; these, however, were not as extensive as in the left temporal convolutions.

The left hippocampus was shrunken (Fig. 3A). Except for an occasional dropping-out of a ganglion cell in Sommer's sector, the nerve cells in this gyrus stained much better than those in the temporal region. In the Sudan III preparation, the white matter contained fatty deposits in the glia and ganglion cells and in the perivascular spaces.

Occipital convolutions: Except for congestion of the vessels and an occasional poorly stained cell, no abnormalities were noted.

Diencephalon and mesencephalon: Sections through these structures showed no abnormalities.

Cerebellum: Many of the Purkinje cells were swollen and showed loss in Nissl substance and peripherally displaced nuclei (Fig. 8).

Medulla oblongata: A number of ganglion cells of the right nucleus paraolivaris dorsalis were swollen. Some of them were balloon-shaped, contained little or no Nissl substance, and their nuclei were displaced to the periphery. The other nerve cells of the olivary nuclei and gray masses appeared normal.

Comment.—The outstanding picture in this case was the marked atrophy of the temporal convolutions, hippocampus and part of the frontal convolutions on the left side. The finer histopathologic picture consisted of distortion in the arrangement of the cytoarchitectural layers of the left temporal lobe, and retrograde changes in the ganglion cells. Of interest in this case was the marked swelling of the nerve cells near the nucleus paraolivaris dorsalis.

The atherosclerotic changes of the smaller cortical vessels were considered as the possible cause of the atrophy. The diencephalic region, which showed similar atherosclerotic changes of the vessels, did not contain any alterations in the ganglion cells. The absence of senile plaques and of Alzheimer fibrillary nerve cells favor a diagnosis of Pick's disease. The appearance of the psychic manifestations rather late in life has been described in a few instances.

CASE 2.—H. Z., a man, aged 42, a peddler, admitted to the Montefiore Hospital, February 1, 1931. There was no familial history of nervous or mental disorders. The patient had been well until July, 1930, when there developed attacks of stiffness of the entire body, preceded by a cry and a few jerks of the forearms. These attacks, which occurred at any time and on an average of two to four times per day, were not preceded by an aura. Six months later he began to fall during these fits. The seizures, which now lasted longer (from two to three minutes), were still unaccompanied by unconsciousness, frothing at the mouth, biting of the tongue or loss of sphincteric control. The convulsions were followed by a period of confusion. Since the onset of the illness the patient had had loss of libido, marked impairment of memory, especially for recent events, and had become silly, irritable, argumentative and euphoric.

Physical and Neurological Examination.—Except for the neurologic findings, the examination was negative. There was generalized diminution in muscle power. The deep reflexes were slightly hyperactive on the right. The sensory examination was negative. The fundi were normal. The pupils were slightly irregular but reacted well to light and in accommodation. There was a slight right facial weakness on mimetic innervation. The tongue deviated slightly to the right.

During a convulsive seizure the patient suddenly began to stiffen and fall backward; the face became deeply congested, and the hands were pulled up in front of the face like a boxer on the defensive. The extremities were in tonic spasm and the eyes remained open and staring. Examination during an attack revealed absence of pathologic reflexes and widely dilated pupils, which did not react to light. The attack lasted about one-half minute, at the end of which time the patient seemed dazed and started walking about aimlessly, smiled fatuously and refused to answer questions or carry out simple commands. The attack, as stated, was not accompanied by biting of the tongue,

clonic spasms or incontinence of sphincters. After five minutes he was more cooperative, but his behavior was sillier than before.

Mental Examination After a Convulsive Attack.—The patient showed lack of attention and cooperated poorly. The memory was poor for recent and remote events, that for recent events being more seriously impaired. He was confused, disclosed a partial aphasia, had difficulty in naming objects (anomia), and perseverated. He could describe the use of common objects such as a pen, pencil, watch and keys, but could not give their names. The greatest difficulty in speech was with the most recently acquired language, English. He stated that today (Monday) was Saturday and could not remember what or when he ate last. He was poorly oriented for time and place. He could not do simple arithmetical sums. He could tell time. Occasionally he talked quite sensibly, while at other times the answers in regard to sequence of events and their significance were poor and he appeared confused. There were no hallucinations, delusions or confabulations.

Three hours after a convulsive seizure, a detailed aphasia status revealed no marked deviation from the normal. There was no difficulty in formulation of speech or comprehension. Simple and complicated commands were carried out well, and the following objects were identified with great facility: glass, pitcher, keys, watch, pencil, tie, shirt, shoes, trousers, finger, nose, fingernail, eyes, matches, cigarette, various coins and envelope. When shown a fountain pen, he described its use correctly, but called it an envelope. He recognized the primary colors. Counting was accurate to 100 and backward from 10 to 1. He told the time correctly and was able to adjust the watch to any specified time. He read German, Jewish and English correctly. Although previous to the illness he could write, he was unable to do so now. The memory impairment during the normal state, however, remained the same as that following a seizure. He was not concerned about his illness, smiled inordinately and showed a tendency to euphoria. Cooperation and attention and ideation were poor. The judgment was impaired.

Laboratory Data.—Encephalographic study disclosed dilatation of the left anterior horn of the lateral ventricle and collections of air in the subarachnoid spaces over the premotor, motor, parietal and occipital convolutions (Fig. 9A and B). The blood pressure was 120/70. The Wassermann of the blood and spinal fluid was negative.

Course.—About three months after admission, the facetiousness, the lack of insight and the impairment in memory and judgment became more marked. He became poorly oriented as to time and place. He wandered off aimlessly in various parts of the hospital. The anomia became pronounced and he had difficulty in naming simple objects at all times. The mental picture at this time was the same as that immediately or days after a fit. The exaggerated deep reflexes on the right and the right mimetic facial became more marked. A diagnosis of frontal lobe neoplasm or Alzheimer's disease was considered. An exploratory craniotomy was performed January 8, 1932, in the left fronto-parietal region. The brain had a slight yellowish discoloration; the veins were more prominent than normal. The relative extreme degree of dilated left ventricle with the absence of increased intracranial pressure pointed

to an atrophic cortex as the probable cause of the epilepsy. Following the operation, the patient pulled off his dressing and on January 15, 1932, developed signs of meningitis and bronchopneumonia, and died January 19, 1932.

Autopsy.—Gross Examination.—Brain: The brain weighed 1300 grams. The dura in the region of the operative flap was thickened, hemorrhagic and contained mucopurulent material. The meninges likewise contained mucopurulent material, and were adherent to the brain. There was a slight subarachnoid hemorrhage over the right premotor and motor convolutions. The right hemisphere was larger than the left. The brain was cut coronally. The convolutions of the left hemisphere were smaller than those of the right; the left temporal and hippocampal gyri showed the greatest amount of atrophy. The *spinal cord* was normal.

Microscopic Examination.—Brain: Complete coronal sections and small sections from various regions of the nervous system were studied by the same methods as those in Case 1.

In coronal sections through the frontal region, the left hemisphere was smaller than the right (Fig. 10A). There were no areas of demyelinization. The third and fourth cortical layers in the first left frontal convolution disclosed a slight pale area. The meninges were thickened and infiltrated with polymorphonuclear leukocytes, plasma and endothelial cells. Occasionally a small cortical vessel in the marginal zone contained a few lymphocytes. In the cresyl violet preparation, the arrangement of the cyto-architectural layers of the first left frontal convolution was distorted. Occasional areas of devastation were seen. The nerve cells throughout all cortical laminæ showed various pathologic changes, such as dropping-out, chromatolysis and peripherally displaced nuclei (Fig. 12). In the second and third left frontal convolutions, in addition to the above pathologic changes, there were also ischemic cell changes; numerous astrocytes and microglia cells were also seen. Slight disintegration of single myelin sheaths near the sixth cortical layer was observed in the myelin sheath preparation. The right hemisphere, except for the meningitis (post-operative), appeared normal. In the Braunmühl and Bielschowsky preparations, senile plaques or Alzheimer fibrillary changes in the nerve cells were not seen.

In sections through the third ventricle, the convolutions of the left hemisphere were smaller than those on the right; this process was most marked in the temporal convolutions (Fig. 10B). In the cresyl violet preparation, all the cortical laminæ of the temporal and hippocampal convolutions were distorted and showed changes similar to those found in the left frontal convolutions. Most of the pathologic changes were in the vicinity of Sommer's sector. A small area of softening consisting of compound granular corpuscles, destroyed ganglion cells and proliferated vessels was found at the border of the lateral and medial nucleus of the left thalamus (Fig. 10B). The parietal cortex also showed slight ganglion cell changes like those found in the temporal lobe.

Coronal sections through the red nucleus disclosed atrophy of the convolutions of the left hemisphere; the temporal lobes and hippocampus showed

the greatest atrophy. The third ventricle was slightly dilated and distorted. The changes in Sommer's sector and temporal lobes were identical with those described in the previous sections. The process in the left parietal area was less marked than in the frontal and temporal convolutions.

In sections through the occipital horns, the convolutions on the left side were atrophied (Fig. 11) and the ganglion cells of the second and third layers of the left fusiform, lingual and inferior temporal convolutions disclosed changes similar to those described in the hippocampus.

In the Sudan III preparation, deposits of fat were found in the nerve cells of the left frontal, motor, parietal, hippocampal, temporal and fusiform gyri; these were more noticeable in the first, second and third layers. Breaking-down of myelin was found in the white matter bordering the sixth layer. In the Braunmühl stain, sclerotic plaques could not be identified. Alzheimer fibrillary nerve cell changes could not be demonstrated by the Bielschowsky method, but the nerve cells of the first left frontal, temporal and hippocampal regions showed argentophilic bodies.

Comment.—Two distinct pathologic processes were found in the nervous system of this case. (1) Convolutional atrophy of the left hemisphere affecting mostly the left first frontal, first and second temporal convolutions and Ammon's horn (Sommer's sector). This process was characterized by chromatolysis of nerve cells and increase in glia cells. Against Alzheimer's disease was the absence of fibrillary changes in the nerve cells and senile plaques. (2) The meningitis was secondary to the operation. The changes in the brain substance due to this meningitis were easily differentiated from the main pathologic process.

CLINICAL CONSIDERATIONS.

Circumscribed cortical atrophy in the presenile psychoses (Pick's disease) has been described clinically in about 70 cases. It occurs twice as frequently in females as in males. The ages vary from about 40 to 65 years. The youngest patient afflicted with the disorder was 38 years old (Richter [3]), while the oldest cases were 79 and 91 years old (Braunmühl [4] and Moyano [5]). Our first patient was 63 and the second 42 years old. The average duration of the illness is from three to six years; in some instances it lasted as long as 12 years. A familial incidence was reported by Grünthal [6] in two brothers, and by Braunmühl and Leonhard [7] in two sisters. Grünthal reported five instances of this disorder in two generations, and Schmitz and Meyer [8] followed the affection in two generations. Familial antecedents were recorded by Scholz,[9] Braun-

mühl,[4] and Pick.[10] The occurrence of psychosis, feeble-mindedness, epilepsy and other degenerative diseases such as Marie's heredo-cerebellar ataxia, Huntington's chorea, amyotrophic lateral sclerosis in other members of families afflicted with Pick's disease was mentioned by several observers (Gans,[11] Anglade,[12] Korbsch,[13] Verhaart,[14] Hascovec,[15] and others). Alcoholism, syphilis, trauma, toxins and infections were considered by some as precipitating factors in the onset of the disease.

The symptomatology does not follow a set rule. The condition has an insidious onset. At first the patient may complain of headache, insomnia and nervousness. The early phase of the disease usually consists of a slight increase in motor activity and asocial conduct. The patient may suddenly show impairment in moral or other judgments, child-like reactions, slight confusion, aimless wandering, facetiousness or euphoria. Some patients, instead of increase in motor activity, may present a loss of initiative of certain duties, dullness, drowsiness and sleepiness. Although the memory is not impaired at first, gradually there is usually loss for recent and less for remote events, poor concentration and clouding of consciousness. The most elementary things, such as what he ate last, are not remembered by the patient. Orientation also becomes markedly impaired. Questions are answered briefly in an obscene or silly manner and repetition of meaningless words or phrases (echolalia) is not uncommon. Delusions, hallucinations and confabulations, frequently observed in Alzheimer's disease, are not common in Pick's disease.

With the gradual loss of memory, the symptoms of a partial aphasia become apparent. Anomia, as in the second case, acalculia and agrammatism occur more frequently than total aphasia. Speech may be limited to a few stereotyped phrases. Perseveration, paraphasia, logoclonia and apraxia are not uncommon findings. Finally the patient becomes completely demented and bed-ridden.

Epileptiform convulsions are not infrequent; these may appear as Jacksonian seizures. The second patient had aphasia and marked anomia lasting for several hours after the seizure. Later in the illness the anomia became permanent. Choreiform movements, sucking and grasping reflexes, and carphologia were also described in a few instances. There are no disturbances in gait; later in the

course of the disease, the gait may become slow and uncertain. The reflexes are normal; occasionally they may be exaggerated and a Babinski toe sign may be elicited. A mimetic facial was observed in the second case. The intellectual impairment interferes with the evaluation of the sensory status. Vegetative disturbances, as noticed in Alzheimer's disease, are less frequently noted in Pick's disease. Encephalographic studies, as in the second instance, show extensive filling of the subarachnoid spaces over the frontal lobes and dilatation of the ventricles. As the lesions occur more frequently in the left hemisphere, the left lateral ventricle becomes enlarged.

The clinical differentiation from Alzheimer's disease is very difficult. Pick's disease begins at about the same age as Alzheimer's. Memory defects in all spheres, such as reception, retention and reproduction, supposedly occur much earlier and are more widespread in Alzheimer's disease. In the late stages, memory is practically gone in Alzheimer's disease, whereas some retention of it can be demonstrated in Pick's disease. Delusions, hallucinations, confabulations, spontaneous speech, palilalia, reiteration and logoclonia occur more commonly in Alzheimer's disease. Epileptic seizures may appear more frequently in Alzheimer's than in Pick's disease. Encephalographic studies in Pick's disease show collections of air limited to the frontal and temporal regions whereas in Alzheimer's disease, the collections are found over the entire subarachnoid space. These air collections may be absent.

Pathological Considerations.

The weight of the brain is reduced and there is usually marked atrophy of the fronto-temporal convolutions; the fissures and sulci are widely separated. Atrophy of the insular, hippocampal, parietal and occipital convolutions has been reported. In the first, as in Ley's[16] (*et al.*) case, the hippocampus was extensively atrophied while the motor and parietal convolutions were involved to a lesser degree. The insular convolutions are frequently involved, the anterior more than the posterior parts. Atrophy of the parietal lobe, as in Case 2, was also reported by Pick,[10] Altmann,[17] Verhaart,[14] and Braunmühl.[4] In parietal lobe lesions, the angular and supramarginal gyri are most extensively involved. Solitary involvement of the occipital lobe, although rarely found, was recorded by Pick,[10] Pötzl,[18] Rosenfeld,[19] and Horn and Stengel.[20] The occipital lobe

in the second case was partially atrophied. Combinations of fronto-occipital, temporo-occipital, or parieto-occipital atrophies have been previously reported. The pole of the occipital lobe usually shows the greatest destruction, while the calcarine region shows the least. The superior temporal is less extensively implicated than the other two temporal convolutions. The left hemisphere is more frequently involved than the right, thus accounting for the partial or total aphasia commonly present in this disorder. As a result of cortical atrophy, a slight internal hydrocephalus is not an uncommon finding. Atrophy of the basal ganglia (Braunmühl,[4] Van Bogaert,[21] and Ley [16] *et al.*) and atrophy of the pons and cerebellum (Verhaart,[14] Case 1) are rarely observed.

Microscopically, the changes occur mainly in the cortical gray matter, although the white matter as shown by others and in the present cases may also be slightly affected. Usually there is distortion in the arrangement of the cyto-architectural layers, especially of the atrophic convolutions. Some authors believe that most of the pathologic changes occur in the first three cortical layers, while others noted alterations in the last three cortical laminæ. Bonfiglio [22] and others, who believe that all the cortical laminæ are affected, are undoubtedly right. Partial derangement with laminar distribution may at times be seen in the less atrophic areas. In the first case, the pathologic changes were equally distributed throughout all cortical laminæ of the frontal convolutions, whereas in the temporal convolutions the changes were most marked in the last three laminæ. In the second case, all the cortical laminæ of the atrophic convolutions were equally affected; the pathologic changes in the left fusiform, lingual and inferior temporal convolutions were in the second and third cortical laminæ. The selective destruction of certain cortical laminæ (Braunmühl,[4] Altmann,[17] Schneider,[23] Jacob,[24] Onari and Spatz,[25] and others) led Martha Vogt [26] to attribute the process to an eumonic form of pathoclisis characterized by a series of regular and constant successions in various sectors.

The ganglion cells of the atrophic convolutions show retrograde changes such as swelling, loss in Nissl substance, peripherally displaced nuclei (Figs. 5 and 12), and pigmentary changes. Chronic and ischemic cell changes may also be present. In the silver preparations, the nerve cells show collections of argentophile bodies vary-

ing in size. The retrograde changes and the deposition of argentophile granules are characteristic of the disease. Acellular areas surrounding the vessels, as in the present two cases, and patchy areas of demyelination have also been reported by others. The demyelination is seldom complete. The white matter near the atrophic convolutions may show myelin sheath and axis cylinder destruction. Mingazini [27] first called attention to the rarefaction of the tangential and radial fibers. These fibers were found intact by most authors. Braunmühl,[4] Schneider,[23] and others believe that primary destruction of fibers is mostly found in cases of rapid progression. Myelin sheath destruction was found in the first case, although the illness lasted over five years. The glia proliferates extensively, as evidenced by the abundance of glia fibers, astrocytes and microglia cells. Fatty degeneration of nerve cells and large amounts of iron deposits are also found. Although the blood vessels in most cases were found normal, hyalin changes, as in the first case, were also reported by Austregesilo,[28] Ferraro [1] *et al.*, and others.

Pathologic changes have occasionally been described in the striatum (Braunmühl,[4] Van Bogaert,[21] Ley [16] *et al.*) and cerebellum (Verhaart [24]). In the second case, a small area of softening was found in the left thalamus. Liébers [29] found a partial atrophy of the thalamus which he believed to be secondary to the lesion in the frontal lobe. Cerebellar lesions were found in Scholz's [9] and Verhaart's [24] cases, while some changes in the Purkinje cells were found in my first case. Senile plaques or Alzheimer fibrillary changes of the ganglion cells, frequently found in Alzheimer's disease and senile dementia, are usually absent in Pick's disease. Senile plaques have been described in Pick's disease by some observers (Kufs,[20] Braunmühl,[4] Altmann,[17] Springlova,[31] Verhaart,[14] Marcus,[32] Guiraud and Cannu,[33] Moyano,[5] Frets,[34] Austregesilo,[28] and Ladame [35]).

PATHOGENESIS.

Several theories are offered to explain the cortical atrophy. The disease has been considered by some observers heredo-degenerative in nature, because of the familial incidence (Grünthal [6] and others), the occurrence in siblings, and the association with other degenera-

tive neural disorders. Whether these hereditary traits are mere chance associations or form part of the clinical picture cannot be definitely stated at present, as the cases recorded are too few in number.

Gans [11] and others, owing to the presence of the atrophic process in the Flechsig association zones and in certain cytoarchitectural areas of Brodman, believed that the pathologic process is limited to phylogenetically younger parts of the brain. Onari and Spatz,[25] and others believe the process is not limited to the phylogenetically younger cortical convolutions, but also to parts of the archipallium. The involvement of the hippocampus in this report and in those recorded by Ferraro [1] and others seems to support Onari's and Spatz's [25] contention. The selective implication of specific cortical laminæ found in some of the recorded cases induced some investigators (M. Vogt,[26] and C. and O. Vogt [36]) to explain the process on the basis of specific vulnerability (pathoclisis) of the nerve cells of these areas. A review of most of the clinicopathologic cases of Pick's disease discloses the absence of involvement of specific cortical laminæ.

Pick,[10] in his original contributions, believed that he was confronted with a form of senile dementia with the possible selection of the association centers. Critchley [37] is of the opinion that there is a precocious aging of the neurons and that Pick's disease and the delayed cerebellar atrophies are examples of a selective involutional process. The physicochemical process responsible for the argentophile substances in the nerve cells as a result of disturbance in the colloidal equilibrium, according to Braunmühl,[4] is common to senility and therefore found in it, in Pick's circumscribed cortical atrophy and in Alzheimer's disease. The circumscribed areas of cellular atrophy, the perivascular accumulations of glia cells and the patchy areas of demyelination, according to Ferraro [1] *et al.*, are sufficient evidence that the lesions in this disorder are angiospastic in character. The hyalin changes in the vessels of the first case, most marked in the temporal lobe, and the observation of similar findings in a number of other cases, suggest that in some cases at least, disease or spasm of the cortical vessels producing cerebral anemia plays a rôle in the pathogenesis of this condition. Spielmeyer has emphasized that the localized degeneration in certain cortical areas, especially in the cornu ammonis, may be due to

peculiarities of vascular supply. Furthermore, the disturbance in colloidal equilibrium may liberate toxic substances of unknown origin acting on the vessels and the surrounding tissue.

SUMMARY.

Two cases of circumscribed cortical atrophy (Pick's disease) are described. The clinical differentiation of this affection from Alzheimer's disease and senile dementia is difficult. Histopathologically, there was atrophy of the left hemisphere in both instances; the temporal and the hippocampal convolutions showed the most extensive involvement. In the second case the atrophy also extended to the parietal convolutions. Practically all the cyto-architectural layers of the affected convolutions were distorted and the ganglion cells showed retrograde and other pathologic changes. In the second case the second and third cortical laminæ were more involved than the other layers. Of unusual interest in the first case were the atherosclerotic changes in the vessels of the left temporal lobe, the swelling and chromatolytic changes of the Purkinje cells of the cerebellum and of some of the nerve cells of the medulla oblongata.

The various pathogenetic theories accounting for the production of this disorder are discussed.

DISCUSSION.

CHAIRMAN BREUTSCH.—I should like to ask Dr. Davison in what percentage is it possible to make a clinical diagnosis of Pick's disease. The symptoms of Alzheimer's disease are also found in various conditions of the senile period, which show an entirely different etiology. Out of 500 cases in the hospital, where I made a postmortem, we did not have a single case of Pick's disease.

DR. DAVID ROTHSCHILD (Foxborough, Mass.).—There is little that I can add to Dr. Davison's excellent description of Pick's disease. I have had no personal experience. It is a very rare disorder. I think Alzheimer's disease is more common.

In attempting a clinical differentiation from Alzheimer's disease, I would emphasize the pronounced affective features, such as perplexed, apprehensive,

agitated states, and acts of hallucinatory periods in Alzheimer's disease, whereas, in Pick's disease, one is more apt to observe an affective emptiness or at least a certain lack of mental productivity in general. Yet, I feel that it is extremely difficult to make a diagnosis on clinical grounds, and I think that this difficulty is probably due to the variable distribution of the chief changes.

If the involvement were constantly limited to one lobe, such as the frontal lobe, we might be able to work out a more or less constant symptomatology, but the involvement varies considerably from case to case.

In attempting to explain the origin of Pick's disease, Dr. Davison has suggested that vascular factors may play a rôle. While observations in a few cases may point in that direction, it seems to me that the weight of the evidence still suggests a degenerative condition independent of vascular factors of primary importance.

It may be that we are dealing with an unusual combination of vascular factors and primary parenchymatous involvement which may perhaps argue for the position of Pick's disease as a sort of border type between a number of other conditions.

In many respects the disease resembles Alzheimer's disease and senile dementia to which it has often been compared. I have seen two cases of Alzheimer's disease with gross circumscribed atrophy as a result of which the brain strongly resembled the brain described in Pick's disease, and, of course, there are cases of Pick's disease which show senile plaques and neurofibrillary changes of the type seen in senile cases and in Alzheimer's disease.

I don't think we can dismiss such observations. I think that they probably represent transition forms between Pick's and Alzheimer's disease.

The histologic changes in Pick's disease themselves are not specific, changes such as these swollen cells which at once were regarded as pathognomonic are not always present.

There is a certain amount of diffuse atrophy in Pick's disease, although this has not as a rule been emphasized. It is interesting to note that Pick's disease is twice as frequent in female as in male patients, and I found a similar predominance in a group of senile patients. On the other hand, in a group of patients with cerebral atherosclerosis, the male patients outnumbered the females by more than two to one.

It seems to me there is a good deal of evidence in favor of Von Braunmühl's conception that in Pick's disease, Alzheimer's disease and senile dementia, and even perhaps in other degenerative conditions, we are really dealing with varying manifestations of the same general type of tissue reaction which affects now one structure and now another.

Dr. Lloyd J. Thompson (New Haven, Conn.).—I think the paper that Dr. Kahn and I presented at the Boston meeting some years ago probably started this series that you referred to. I remember our paper at that time agreed very much with what Dr. Davison said today. However, we did point out that convulsive seizures, focal neurological signs, outside of aphasia

and associated things, and arteriosclerosis was decidedly rare in Pick's disease, and, therefore, this second case that was given today certainly is an unusual case because it combines all of those things.

I followed the literature since to some extent, and there is a great deal in German literature indicating more and more the possibilities of heredity in this disease. They have uncovered many cases in which there is a definite hereditary element.

DR. MAX H. WEINBERG (Pittsburgh, Pa.).—I should like to ask: Were these cases uncinate in type in the second group you described? Was there also a change in the rod cells?

Another question in general is how can we in a condition like this, which seems to be so far widespread throughout the entire brain, determine the definite symptoms? The symptoms should depend on what areas are involved.

DR. CHARLES DAVISON (New York, N. Y.).—All I can say in reference to the Chairman's question is that he is quite correct: clinically it is difficult to diagnose Pick's disease. As a matter of fact, a number of observers at our institution have considered the possibility of cerebral neoplasm in the hippocampal or temporal regions. In answer to Dr. Weinberg, I might say that my patients had no uncinate fits. We considered the diagnosis of Alzheimer's disease and cerebral neoplasm because of the youth of the patient, aged 42, and the encephalographic findings. There were no localizing signs, but because of the right mimetic facial, the operation was done on the left.

Clinically, diagnosis is difficult. As to the various theories enumerated by Dr. Rothschild and included in my paper, it is arbitrary as to what really comprises the pathogenesis of these various disorders. Whether we are dealing with some colloidal disturbance of the chemistry of the brain at this particular age, or with vascular changes, as was demonstrated in a few instances, are questions which will not be solved until we have studied a greater number of cases.

The changes, as you will remember, in these cases were not those found in paresis. In paresis there is a disarrangement of the cortical layers, but there are also perivascular infiltrations, usually of the lymphocytic variety. Such changes were not found in our cases. As to the rod cells which are frequently described in paresis, I might say that they can be found in any type of reaction of the nervous system. In addition the serology of the blood and spinal fluid in both instances was negative. The histopathology was certainly not that seen in cerebrospinal syphilis.

EMOTIONAL FACTORS IN THE REHABILITATION OF THE PHYSICALLY DISABLED.*

By LEON REZNIKOFF, M. D.,
Clinical Director, Hudson County Hospital for Mental Diseases, Secaucus, N. J.

For many years the problem of rehabilitating the physically disabled has been handled almost entirely from the physical point of view.

When, as a result of an accidental injury or disease, a man lost a leg or an arm, he was treated at a hospital and later supplied with a more or less workable artificial limb. If he had to spend a few weeks or months in the hospital, the chief concern of the physicians was to do the best they could surgically to correct his deformity. If the patient was indigent and there was a social agency cooperating with the hospital, their only concern was to purchase a serviceable artificial leg or arm for the patient. Little attention was paid to his occupation prior to the injury, whether or not the artificial limb would unable him to continue with his previous work, or whether the industry in which he had been employed would give him the same position that he had had before the injury occurred.

Still less consideration was given to the question how the disabled man would react to his new situation, and certainly no thought was given, at least from a practical point of view, to what the individual's emotional reaction would be toward his crippled body.

Gradually it has been realized that correction of orthopedic deformity alone is not sufficient to return the injured individual to the community as a self-supporting person.[1] In recent years vocational examiners and social workers have entered the field of rehabilitation of the physically disabled, and it is only a few years since psychiatrists and psychologists have begun to occupy themselves with problems of this sort. The work of V. V. Anderson in industrial psychiatry [2] is well known. His study of the personnel

* Read at the annual meeting of The American Psychopathological Association in conjunction with the ninety-third annual meeting of The American Psychiatric Association, Pittsburgh, Pa., May 10-14, 1937.

of large industrial and commercial organizations from a psychiatric point of view has brought about remarkable results.

Since 1920 almost every state in the Union has established a special bureau to care for the physically disabled. In some states these vocational or rehabilitation bureaus are closely affiliated with the state department of education; in others they function as independent units of the state government. There are also a few which are maintained by private organizations with the aid of endowed funds. In the State of New Jersey the Rehabilitation Commission functions as a part of the State Labor Department and has branches, known as rehabilitation clinics, in several of the larger cities.

This report deals with the application of psychiatric principles in connection with the work of the New Jersey Rehabilitation Clinic maintained at Newark, New Jersey.

The objective of the clinic is to return to productive working capacity all individuals who have become physically handicapped as a result of congenital and acquired deformities and disabilities.[3] Disabled persons referred to the Rehabilitation Commission for help suffer from all degrees of physical disability. Some have minor defects which cause little incapacity; others are so severely and permanently disabled that to the casual observer they seem to offer only the slightest possibility for physical restoration to productive capacity. Not infrequently they have multiple disabilities of both physical and mental nature.

After the physical defects have been corrected as much as possible, the handicapped person is trained at the workshop maintained by the clinic, or arrangements are made to teach him some trade or occupation elsewhere which will not interfere with his particular deformity.

It is necessary to make a complete survey of the applicant's potential assets and liabilities in order to obtain a comprehensive picture of his case which will eliminate as much as possible any element of error or guesswork.[4, 5] One interview by a personnel representative with a single medical examination and a superficial appraisal by a vocational examiner are not adequate measures to judge the adjustment possibilities of the handicapped individuals.

In carrying out this work the following technique has been developed: When a client applies to this clinic for rehabilitation a complete history is taken by a trained social worker. The appli-

cant is then examined by the medical director, and undergoes such vocational and psychological tests as may be indicated in his case. A complete study of his personality make-up is made by a psychiatrist. His emotional reaction towards the disability and work is particularly investigated.

This mutual cooperation of several experts in their respective fields has been so fruitful that it has been decided to hold conferences at frequent intervals when each individual case can be studied and the best plan for rehabilitation worked out. The conference is composed of the medical director, assistant director of the clinic, vocational examiners, psychiatric social worker, psychologist, and psychiatrist. Attempts are made to diagnose the difficulties of the client, to evaluate his assets and to visualize his entire life situation.

Psychological elements not infrequently play a paramount part in the ability of the crippled individual to solve his adjustment problems.[5] Emotional attitude toward disability, work and life in general must be seriously considered if the attempts at rehabilitation are to have any measure of success. The total personality of the disabled person must be studied from all angles—physical, mental and social—in order to achieve a complete picture of the entire situation. Repeated examinations, extensive study and follow-up of these cases have shown that the predominant factor in failure to make a satisfactory social and vocational adjustment is not the physical handicap itself, but the neurotic attitude towards the disability. Numerous case histories indicate that there is no direct correlation between physical condition and vocational adjustment, but there seems to be a definite correlation between the emotional attitude of the handicapped person on the one hand, and vocational capacity and adjustment on the other.

The following case histories, taken at random from the files of the rehabilitation clinic, illustrate clearly the need for psychiatric approach to the problems of the physically disabled. Because of lack of space, the histories have been abbreviated as much as possible.

Case of H. K.—An 18-year-old girl, suffering from slight shortening of the left leg and mild scoliosis, was referred in 1933 to the clinic for rehabilitation. She received corrective orthopedic treatment, her shoe was raised on the left side, and a corset support was prescribed. The orthopedic surgeon re-examined her some time later and reported that her scoliosis was com-

pletely corrected and that she was in no need of further treatment. She walked with only a very slight limp.

It was then arranged by the vocational examiner to give her a course of commercial training at a business school. This was prior to the time when psychiatric service was established.

After two years of business school study, she turned to the rehabilitation clinic a complete failure. She was very much retarded in her progress and was unable to make the grade despite her conscientious efforts to do so. In the course, which ordinarily takes from nine to twelve months, this girl had been applying herself for two years. Unsuccessful in competition with her classmates, she became very unhappy, developed feelings of inferiority and fears that she would be unable to accomplish the necessary work. She attended classes under a feeling of compulsion and dislike.

Psychiatric examination revealed that the main problem of this girl was not her slight physical deformity, but limited intellectual development and emotional attitude toward the school. She had an I. Q. of 88, and with this dull average mentality, it was absolutely impossible for her to succeed in clerical work; therefore it was only natural for her to fail in the subjects which she had taken in the business school for two years.

Her mother had received practically no education but was ambitious for her daughter to gain by specialized education; she insisted and encouraged the daughter to go on with the business school training.

The girl was unable to meet the parent's desires and became emotionally upset, apprehensive, unhappy and maladjusted. She said, "My mother is disappointed that it takes me so long. It makes me feel bad. I am a terrible failure." She was ashamed to meet other classmates and friends, became extremely shy, sensitive and introverted, and had frequent crying spells.

After her case had been discussed at the clinic conference, and the reasons for her emotional instability and failure at business training pointed out, it was decided to arrange for her a period of employment training whereby she could gain experience and some security. She was placed at a home for crippled children where she could participate in the care of the children, and at the same time gain experience in the operation of a switchboard. She was interviewed some time later and appeared to be contented and making a satisfactory adjustment.

Without psychological and psychiatric studies, many haphazard attempts would have been made in the wrong direction at the expense of the rehabilitation clinic, or some other social agency, without helping the girl to achieve any degree of social adjustment.

CASE OF P. M.—This 48-year-old man was sent to the rehabilitation clinic because of almost complete loss of hearing following a head injury in 1927. Prior to this accident, the man was employed as a foreman in a factory and was considered a capable, steady, diligent and productive worker.

After the accident he was unable to adapt himself to any work, and when he came to the rehabilitation clinic the vocational examiner suggested training as a cabinet maker or carpenter in the workshop maintained by the clinic.

However, he failed to make any progress and was referred for psychiatric study. Our examination revealed that the man was suffering from traumatic psychosis. Following the head injury he had been unconscious for four days and gradually developed severe personality changes, had attacks of dizziness, irritability and irascibility, marked emotional instability, auditory hallucinations and an antagonistic attitude toward his relatives and employers which bordered on a paranoid trend.

This man was in urgent need of psychiatric care, and therefore all attempts at ordinary rehabilitation, to make him self-supporting, were doomed to failure. He was referred to the psychopathic ward of a local hospital for observation.

CASE OF A. M.—A 21-year-old crippled boy came to the rehabilitation clinic anxious to get aid in vocational training and placement. He had had infantile paralysis in childhood, which left him with residual signs involving the spine and left lower extremity.

According to the report of the vocational examiner, the boy had completed his senior class in high school and had expressed the desire to enter a business school for a course in secretarial study. Because of his poor marks in school, which ranged only from 70 to 75, it did not seem to the vocational examiner after a cursory examination, that the boy was fit for further study at a business school. Yet the psychologist at the rehabilitation clinic reported an I. Q. of 123, and the psychiatric social worker, after careful study of his home situation, was able to throw light on the causes of the boy's poor scholastic standing. With a history of physical disability from the age of two years, the boy had had to make a difficult emotional adjustment which was aggravated by constant friction and separations on the part of his parents, economic pressure and lack of social approval. He became sullen, stubborn, sulky and irritable, had no confidence in himself, and developed a constant feeling of fear and insecurity.

Following a few interviews with the psychiatrist, it was decided to adopt a course which would build up the boy's morale and confidence in himself. As an experiment, he was placed on a part-time basis in the secretarial school which cooperates with the clinic, and after a short period of observation, made such good progress that he was put on a full-time schedule.

CASE OF E. S.—A 45-year-old feeble-minded man had been self-supporting all his life despite retarded intellectual development. With an I. Q. of 50, he did fairly good work as an unskilled laborer in factories and on farms.

Recently he sustained a compound fracture of the right leg which caused slight shortening of the right lower extremity. Because of this disability he was referred to the rehabilitation clinic.

This man has made an excellent adjustment to his recent disability by taking it lightly with the idea that, at the present time, he is practically in as good condition as he has always been.

Because the man was eager to cooperate, and did not consider himself an invalid, it was comparatively easy to place him as a helper on a farm where he is reported as doing well.

This case illustrates that even under the present difficult economic conditions a man can be successfully rehabilitated in spite of serious physical defect and retarded mentality.

SUMMARY AND CONCLUSIONS.

1. The function of the New Jersey Rehabilitation Clinic is described.

2. Advantages of application of psychiatric principles to the work with physically disabled are pointed out.

3. The New Jersey Rehabilitation Clinic is the first of its kind to make a complete psychologic and psychiatric study of clients applying for rehabilitation, in addition to social and vocational investigation.

4. Psychiatric study at this clinic has contributed greatly towards the efficiency of the work in rehabilitating the crippled and disabled, and has proven to be of educational value to the vocational examiners and other personnel.

5. Because of early elimination of cases not adapted for ordinary rehabilitation, the new approach of the clinic has helped to save considerable money for the state, which by far exceeds the small expense required for the services of the additional personnel.

INTERPRETATION OF THE ELECTRICAL ACTIVITY OF THE BRAIN.*

By HALLOWELL DAVIS, M. D., Boston, Mass.

The idea that electricity is intimately associated with the activities of the animal body is as old as our knowledge of electricity itself. We have only to recall the original observations of Galvani in 1786 which showed that the nerves and muscles of frogs could be stimulated by what was subsequently recognized as the electric current, and also the controversy between Galvani and Volta as to whether or not the animal tissues themselves generated this electricity, to realize this early association. However, in the enthusiasm for the development of the new science of electricity on a purely physical plane, these early observations were largely forgotten, and the study of electrophysiology was confined to a few physiological laboratories. This sequence was undoubtedly inevitable, since accurate observations of animal electricity could be made only after the fundamental principles of electrical energy had been established and technical methods for measurement had been devised.

During the intervening years, with the gradual improvement in methodology, a few fundamental principles became clearly established—first, that electricity could not only stimulate animal tissues, but also that it was actually generated by them, and that it was particularly associated with activity. A nerve or muscle must be alive to be a source of current. If we injure part of a cell and connect injured and uninjured regions with a sensitive galvanometer, current flows between them, and it is generated by the normal living tissue and not by the dead tissue. Furthermore, during activity such as the contraction of a muscle or the passage of an impulse along a nerve, there is an abrupt fluctuation in this steady flow of

From the Department of Physiology of the Harvard Medical School.

current. All of us, I believe, have heard of these so-called "action currents," which in physiological laboratories have proved invaluable tools for the study of nerve impulses and of muscular activity. Each living cell acts as a tiny battery which under conditions of physiological activity sets up a flow of electricity in the surrounding tissue. We must realize that this electrical current in the surrounding tissues is not identical with the nerve impulse, but is simply a by-product of activity, like the noise of an automobile. If enough cells become active at the same time and are so situated in relation to one another that their currents reinforce instead of neutralizing one another, the flow of current may be sufficiently intense to be detected at the surface of the body, provided our electrical instruments are delicate enough. The best example of this is the electrocardiogram which may be led off from the limbs, quite remote from the heart itself, but which reflects accurately the moment of activation of the various parts of the heart. The heart is a particularly favorable organ for such electrical manifestations, since it acts physiologically as a unit, and its various fibers contract in ordered sequence at nearly the same instant. By a study of the electrical record so obtained, the clinician may gain valuable information as to the sequence of activity in auricle and ventricle, and the relative development of various parts of the organ. The origin of a beat from an unusual position, or damage to cardiac tissue from blockage of part of the coronary circulation, is revealed by an abnormal pattern of electrical activity.

The electrocardiogram has so far been the chief contribution of electrophysiology to clinical medicine, and may serve as a model in our minds as we seek to interpret the meaning and possible practical significance of the electrical activity of the brain.

To return to the fundamental principles of electrophysiology, we must be perfectly clear at the outset of another basic concept. Although we may properly speak of muscle cells and nerve cells as electrical batteries, since they generate the electrical currents which we have just described, we must not be misled into thinking of the nerve fibers as electrical conductors analogous to the wires in a telephone system. Electricity can flow in nerve fibers, to be sure, just as it flows through muscles and skin when we register the electrocardiogram through electrodes attached to the arms, but this

flow through tissues is diffuse, and the current is not confined to the nerve fibers, as a current in the telephone system is confined to a metallic wire. Rather we must think of each bit of nervous tissue as itself a tiny battery or charged condenser, ready to liberate electricity as the wave of physiological activity which we call the "nerve impulse" passes along it. The nerve impulse has concomitant electrical manifestations and these electrical disturbances are probably part of the mechanism by which the nerve impulse advances from point to point along the fiber, but *the nerve impulse is much more than the mere passive flow of electricity along a conductor.* The nerve impulse has been aptly compared by Keith Lucas to the burning of a train of gun-powder, with the liberation of energy at all points along the train. In the nerve the energy so liberated is electricity as well as heat, but the fundamental analogy is valid. The electrical discharge tells us when the wave of activity reaches a particular point, and also tells us something of the nature of that activity, but the wide difference between the velocities of conduction of electricity and of the nerve impulse should make us immediately aware of fundamental differences between the two.

We must avoid thinking of the brain as a mere reservoir of energy—electrical energy perhaps—which because of its very content of electricity might tend to discharge when opportunity offers. We cannot hope to measure "nervous energy" in terms of electrical volts and amperes. Such analogies are purely specious and lose sight of another fundamental fact, which is that *the ease with which a nerve or muscle cell may be stimulated to activity by an electrical current or any other stimulus bears only a distant relationship to the amount of electricity which will be liberated when the cell becomes active.* "Nervous energy," in the popular sense, should be thought of in terms of how readily various parts of the nervous system may be called into action, rather than how much electricity is generated as a result of that activity. It is the same distinction that we make between how hard it is to pull the trigger of a pistol and what may be the velocity of the bullet which it fires.

The electric current generated by a nerve impulse is minute and brief. Its potential is measured in terms of thousandths of a volt

and its duration is about a thousandth of a second. A single nerve impulse in a single fiber can readily be detected and studied by means of modern amplifiers, but even with the best of instruments this is possible only if the nerve can be dissected free from surrounding tissues and laid directly on our recording electrodes. Even the activity of the brain as a whole only yields potentials measured in terms of millionths of a volt when we apply electrodes to the outside of the human head. Fortunately, our amplifiers are now competent to deal with such tiny electrical fluctuations, and, as Adrian has put it, the introduction of modern amplifiers has been for electrophysiology what the introduction of the compound microscope was to anatomy. Small as these currents are, we can now record them, measure them, classify them, and undertake to associate various types and patterns of electrical activity with other activities of the organism. We shall describe a few of these patterns in more detail in a moment, but I wish to emphasize the fact that they represent the sum of the activity of myriads of individual cells in the brain. In fact, until Hans Berger in 1929 showed experimentally that it was possible to record significant electrical patterns from the human head, most electrophysiologists had refrained from even making the attempt, so sure were they that activity of the individual cells must necessarily be so disorganized and scattered in time and direction that they would cancel one another out completely, as far as any external detection was concerned. The fact that a pattern of total activity can actually be detected implies an organization of the activity of many brain cells. We know from anatomical studies that in the gray matter there is a definite anatomical orientation and grouping of cells into recognizable layers, but the degree of physiological organization of activity which we can infer from actual electrical records was not suspected. In a sense, therefore, we are faced with a new phenomenon—the physiological organization of activity of cortical cells as indicated by their electrical activity; and, for the interpretation of the pattern which we find, we must start from the very foundations of empirical observation. Our guiding principles are that the electricity is undoubtedly generated by individual cells, that external electrical fluctuations indicate fluctuations of physiological activity, and that we must be dealing with an organization among myriads of individual elements.

We might add that laboratory studies have shown quite conclusively that the electroencephalogram, as we call the record of electrical activity led off from the head, depends upon cortical activity. It is a type of activity characteristic of gray matter rather than white matter, and the same kind of activity can be detected from gray matter deeper in the nervous system—in thalamus, cerebellum, and spinal cord—but because of its favorable anatomical situation near the surface it is the cerebral cortex whose activity registers in our instruments. This characteristic activity of gray matter tends to be more or less clearly rhythmic, and its rhythm is relatively slow compared with the very brief duration of the impulse in a nerve fiber. Furthermore, there is good evidence that this rhythmic activity may originate spontaneously in the cortex or other centers, in absence of any recognizable external stimulation. Nerve impulses reaching the centers may, however, significantly modify the activity already in progress in those centers, and likewise activity may be modified by changes in the physiological environment, such as lack of oxygen, the presence of drugs, and so on.

What are some of the patterns of electrical activity exhibited by the human brain and what empirical meaning can we give to them? Young as this type of study is, a few generalizations now seem well established—thanks to the work of such investigators as Berger, Adrian, Kornmüller, Jasper, Loomis, Gibbs, and many others. Fig. 1 shows samples of normal records taken from several different individuals under standard conditions and illustrates what we may consider a range of normal variation. All of these were taken from the occipital region, but we may say at once that all parts of the cranium yield fundamentally similar patterns. To be sure, the large, smooth, ten-a-second, so called " alpha " waves so prominent in the upper record are likely to be less prominent and less plentiful at the top of the head or in the frontal regions, while the smaller, faster waves at 20 to 30 a second tend to be slightly more prominent in the latter regions. Animal experiments by Kornmüller [8] suggest that more or less typical patterns may be assigned to particular anatomical fields and correlated with the type and arrangement of cells found there. The intact skull and scalp, however, obscure any sharp boundary zones which may exist

in the human brain, and the similarity of records from different parts of the head is more impressive than their differences.

Normal human adults vary between the two extremes illustrated in the figure—on the one hand, an almost continuous exhibition of ten-a-second waves as long as the eyes are closed, and, on the other hand, no alpha waves whatever. Of the normal individuals we have examined, about a half of them show clean-cut alpha waves more than half of the time; about one-quarter yield them more than 75 per cent of the time; while another quarter are less

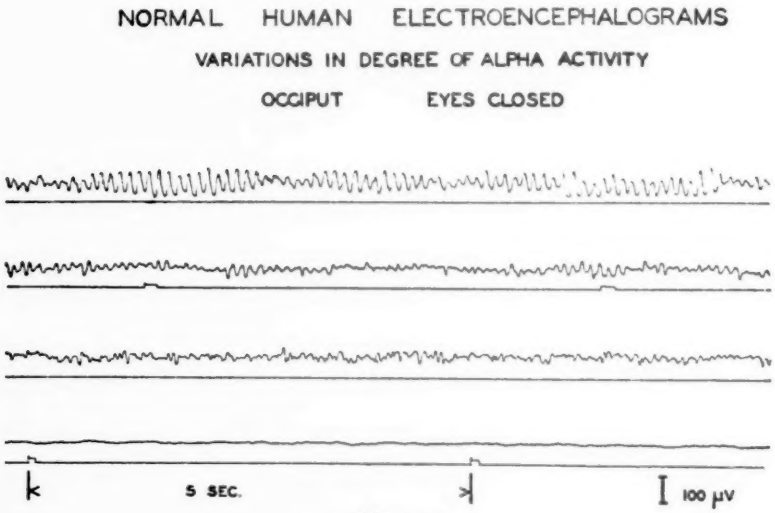

FIG. 1.

than 25 per cent. It is interesting to speculate with what other characteristics of the individual—perhaps even psychological traits—this difference of electrical behavior may be correlated. Lemere [9] makes the interesting suggestion that individuals of the manic-depressive type tend to have good alpha waves, while the schizophrenics do not, but we must still regard any such suggestions as tentative working hypotheses. Our own studies, not yet published in detail, indicate that there are too many exceptions to allow us to be satisfied with the simple rule as here stated. We personally feel confident, however, that a very significant relationship does exist between the presence of alpha waves and at least one basic psychological trend.[11]

To return to well-established facts, we do know that presence or absence of the alpha rhythm is not correlated with intelligence. In children less than 10 years of age, the rhythm tends to be slower than in adults, but may nevertheless be very clearly defined. Although different individuals differ widely from one another in respect to the alpha waves, and also other features, such as voltage, general pattern, and sharpness or roundness of wave-form, a given individual tends to reproduce his own record on successive tests. Minor variations do occur, and we must not think of the electroencephalogram as having the individuality of a fingerprint. We can more legitimately compare it to the individuality of a person's voice, which in spite of differences in loudness and tone or the words which he may speak, we can nevertheless recognize with a fair degree of certainty. It is also a matter of some interest that identical twins have so far (14 pairs) yielded closely similar patterns [3] —as similar indeed as their physical appearance or their voices. This confirms the idea of a fundamental organic significance of the individual electroencephalogram.

Just as individuals differ from one another in respect to the amount of alpha rhythm which they exhibit, so the amount of alpha activity varies from time to time under different circumstances. Opening the eyes is a sure way of checking it, at least momentarily. The onset of drowsiness will also inhibit it, and any sudden unexpected stimulus which startles the subject, or sometimes conditions of embarrassment or apprehension, may do the same. It appears to be a labile indicator of something, but as yet we know not what.

Considering extremes of activity and depression, we find opposite characteristics in the electrical record. Overactivity of a pathological sort, illustrated by strychnine poisoning in animals, and the grand-mal epileptic seizures seen in humans [4] gives a high-voltage record full of sharp spikes in quick succession. The electrical activity tends to build up to a climax in parallel with the muscular spasms or clonic jerks and to show a period of very slight activity during the relaxed stupor following a seizure. In general, overexcitation of the cortex seems to be revealed by quick sequences of sharp spikes at relatively high voltage.

States of physiological depression are associated with slow irregular waves at perhaps two to four a second. These waves may attain as high voltages as the epileptic spikes, but differ completely from them in their slow, rounded contours. The various depressed states that show slow-wave activity include not only anesthesia,[5] particularly with the barbiturate drugs, but also cortical anemia,[4] or anoxemia from any cause, hypoglycemic shock induced by insulin,[6] and finally normal sleep (Fig. 2). The most extreme case that we

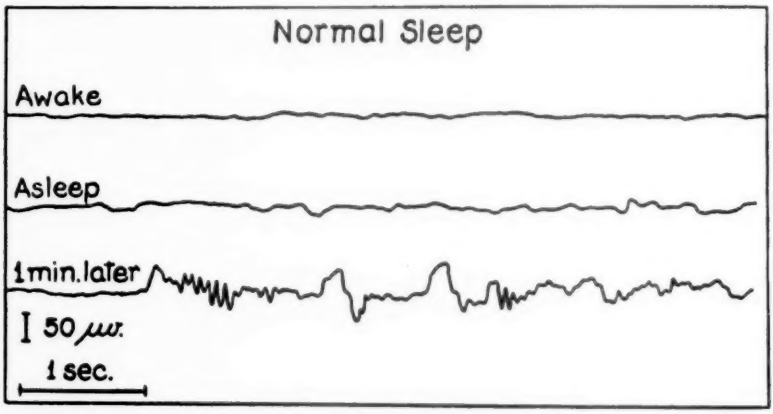

FIG. 2.

have studied personally was a long-continued coma following carbon-monoxide poisoning (Fig. 3). Petit-mal epilepsy is associated with an interesting and characteristic combination of the sharp high spike of overactivity alternating with the slow, rounded dome of depression.[4] We believe that it is significant that all of these depressed states are associated with mental confusion or complete loss of consciousness.

It is too early to attempt to interpret in terms of particular cells or cortical layers these various types of activity, which we have tentatively designated as the normal, the overactive, and the depressed. Neither have we time to review in more detail the many important and significant observations from many laboratories which are laying the groundwork of empirical observation and physiological analysis. In time, we may understand the relation of these

electrical events to states of central excitation and inhibition and perhaps even to consciousness. Working hypotheses are necessary as we advance, but our theoretical interpretations must not violate established principles of neurophysiology, and our generalizations must rest upon carefully controlled empirical relationships.

ELECTRICAL SIGNS OF CORTICAL FUNCTION IN EPILEPSY AND ALLIED DISORDERS.*

By HERBERT H. JASPER, Ph. D., D. és Sci.,

AND

IRA C. NICHOLS, M. D.,

Providence, R. I.

Psychiatry and neurology owe a great debt to Dr. Hans Berger, director of the Psychiatric Institute and Hospital at Jena, who demonstrated to the world, after years of careful scientific work, that it is possible to obtain important electrical signs of the functional condition of the human brain from electrodes applied to the unopened skull. The discoveries made possible by the new technique of electroencephalography not only give us new insight into dynamic aspects of normal brain function but also make possible the observation of some of the phenomena associated with the abnormal brain function accompanying many neurologic and psychiatric disorders.

We have been using the method of electroencephalography in the routine examination of patients admitted to the Emma Pendleton Bradley Home for over two years and have made supplementary studies on selected patients from neighboring institutions. A total of 430 examinations have been made on patients with various neurologic and psychiatric disorders, 115 of which were on patients diagnosed as suffering from epilepsy. Two hundred and sixty control experiments have been conducted on normal human subjects with a number of animal controls (cats); in the latter it was possible to obtain the records from electrodes placed directly in contact with the cortex. The present report is concerned with the

* Read at the ninety-third annual meeting of The American Psychiatric Association, joint session of the Section on Convulsive Disorders and the American Chapter of the International League Against Epilepsy, Pittsburgh, Pa., May 10-14, 1937.

Research supported by a grant from the Rockefeller Foundation.

contributions that these studies have made to our understanding and clinical treatment of epilepsy.*

Schon and Kornmüller (1932) (reference in Kornmüller [1]) were the first to describe brain potentials of a particular form occurring in experimental epilepsy in animals as induced by drugs or hyperventilation. Fischer [2] and Fischer and Löwenbach [3] report additional observations on large explosive potential variations in the cortex of the rabbit induced by similar methods, and also by direct electrical stimulation of the brain. Adrian and Matthews [4] report an interesting analysis of seizure waves in the cortex of the rabbit brought on by drugs. These waves were of exceptionally large amplitude and were conducted over the surface of the cortex at a definite velocity of about 10 to 15 cm/sec. They were apparently conducted from foci to adjacent regions and occasionally were sufficiently large to involve the entire cortex. An interesting description of the significance of these epileptiform waves and their spread from one region to another is given in Adrian's summary before the Royal Society in 1935.[5]

Kornmüller [1] presents a rather complete study of various convulsive states in different cortical and subcortical centers in the rabbit and monkey with convulsions being brought on by various drugs, mechanical irritation, excessive afferent stimulation and hyperventilation. He also presents an interesting discussion of the application of these findings to various theories of epilepsy. An abstract of his findings follows:

(1) Seizure waves occur as a result of excess stimulation of a given region or as a result of changes in the excitability of cortical tissue due to drugs or to changes in metabolic state such as those occurring in hyperventilation. (2) Electrical activity in the convulsive condition in terms of electrical energy recorded is increased as high as 20 times the normal level of activity. (3) The sequence of changes in a severe convulsion appear to be as follows: (a) Changes in the spontaneous activity often characterized by an increased frequency and amplitude. (b) Large rhythmic slow discharges often composed of one or more spikes combined with slow smooth waves regularly repeated at frequencies from 2 to 5 per sec. (c) The frequency pattern of the slow discharges changes during the course of a seizure, the waves tending to be of longer duration and lower frequency towards the end. (d) The

* Interpretive principles will be based upon the results of many other investigators including Dr. Howard Andrews, Dr. Margaret Rheinberger, and Dr. Philip Solomon of our laboratories. Dr. William Hawke also took part in some of the work with epileptic patients.

rather abrupt cessation of the electrical activity is followed by a period of abnormal quiet which he has called the period of "exhaustion." This is followed by a slow return to the normal brain activity for a given region. The length of the "exhaustion" period is proportional to the severity of the "explosive" period. (4) An epileptic state beginning in a restricted cortical area tends to be definitely confined to this area. The border of a new architectonic area seems to act as a barrier to the spread of the seizure which, however, may be passed if the activity in the epileptogenous zone becomes sufficiently great. The seizure waves may pass synapses through which normal impulses do not pass. (5) Some indications are given that the seizure waves from different brain areas vary somewhat in accordance with the architectonic structure differentiating these areas. Seizures elicited in a variety of ways give the same type of waves from a given brain region, although they may be varied by changing the metabolic state of the cortex. (6) The use of a drug producing generalized convulsions shows that different brain areas have different thresholds, some being discharged much more easily than others. (7) One center may become a pace-maker for epileptic discharges in other parts of the brain. (8) Seizure waves were also observed in the subcortical hypothalamic nuclei. (9) Some correlation was found between the seizure waves from the precentral region and the rhythm of clonic movements in the forearm as determined by simultaneous records of brain potentials and muscle action potentials in the rabbit. (10) Isolated seizure waves were recorded from the precentral region of the rabbit in the early stages of hyperventilation, the periods between these sporadic waves showing a fairly normal type of brain activity.

Due to the marked increase in magnitude of the electrical potentials developed at the cortical surface during an epileptic attack it is very easy to obtain a rough indication of their nature through the unopened skull in man if there are not too many artifacts introduced by the convulsive movements. Berger [6, 7] found that the sequence of events in a grand mal attack in man was similar to the description given by Kornmüller for experimental attacks in animals. Foerster and Altenberger [8] obtained very large rhythmic potentials of similar nature by recording directly from the cortex in man during a brain operation. The work of Gibbs, Davis, and Lennox,[9] and Gibbs, Lennox and Gibbs [10] has served to establish the general clinical value of the E. E. G. in epilepsy. Sequences of periodic discharges of a characteristic form signalize the approach of an attack, persist throughout the attack, and occur sporadically in "larval" forms during the periods between the overt clinical seizures. With multiple recording systems permitting the simultaneous observation of the electrical activity from several

restricted head regions, a standard technique developed by Jasper and Andrews [11, 12, 13] and applied extensively to epilepsy by Jasper and Hawke,[14] it is possible to detect local epileptogenous zones and to follow the spread of a seizure from one region to another. This confirms in man the type of spread described by Kornmüller and Fischer in animals. The more practical significance of these findings will be summarized as they appear to shed light on certain clinical problems related to epilepsy.

DIFFERENTIAL DIAGNOSIS.

Gibbs, Lennox, and Gibbs [10] have stated that the form of the seizure waves in petit mal attacks is definitely pathognomonic for petit mal epilepsy. No such regularly repeated sequence of waves has been reported by Berger from his studies of other pathological conditions and the form and frequency of some of the seizure waves obtained by Kornmüller in animals were similar to the spike and slow wave sequence obtained during a petit mal attack. Jasper and Hawke [14] compared records from 55 epileptic patients with records taken under the same conditions from 105 patients with various disorders of the central nervous system not diagnosed as epilepsy. The spike and slow wave sequence at 2-4 per second was found characteristic of the E. E. G. at some time during most petit mal attacks with rather wide variations in form throughout the attack and also with marked differences between individual patients. In some cases a very mild attack showed only smooth waves at about three per second of about the same form as the normal alpha waves which occurred at 10 per second between seizures.

It was found, however, that the spike and slow wave sequence did appear in patients who had not been diagnosed as epileptic from clinical observations, that is, they did not have paroxysms of convulsive movements or loss of consciousness. This raises the question as to whether to base diagnosis upon clinical criteria or upon the E. E. G. The discovery of a similar wave form in a group of behavior problem children [15] who had not been suspected of epilepsy previous to the E. E. G. examination is an example of this difficulty. These children did show many of the personality deviations and mental conditions often associated with the epileptic

personality, but should this be called epilepsy? There is also the large spike and slow wave form described by Travis and Malamud [16] in two stutterers during a spasm in speech. Should these cases also be called epileptic? We are here dealing with pathological conditions of the brain quite similar to those found in patients with paroxysmal loss of consciousness or convulsive movements but we feel that, at least at present, the diagnosis of epilepsy cannot be made upon the basis of the presence of seizure waves in the E. E. G. We feel that it is better to base the diagnosis of epilepsy upon clear clinical as well as electroencephalographic evidence and to speak of these disorders functionally associated with epilepsy by the electroencephalographic findings as *allied disorders* rather than true epilepsy.

On the other hand in our experience all cases of epilepsy (so diagnosed by the usual clinical criteria) have shown clearly recognizable seizure waves of some form in the E. E. G. during a seizure, and many cases showed them even between attacks. We have had seven patients referred for examination because their epileptiform attacks were questionably hysterical rather than genuinely epileptic. In two of these patients we found the E. E. G. within normal limits when taken between attacks and we were unable to induce a seizure with hyperventilation. This evidence is not conclusive, however, since in some patients with genuine grand mal attacks we have also found the E. E. G. within normal limits between attacks although marked changes are ordinarily easily induced by hyperventilation. A third patient was reexamined until we were able to get a record throughout one of her typical " spells." The E. E. G. showed only those changes typical of a normal excited individual so that we felt justified in giving the diagnosis of hysteria on the basis of the E. E. G. findings. A very cleverly simulated attack might, of course, produce movement artifacts closely resembling seizure waves but we have not seen such artifacts which could not be distinguished from seizure waves if adequate controls are taken during the examination. The four other cases showed sporadic seizure waves even between seizures.

The Question of Surgical Intervention.

Six different methods of localizing a restricted region of the head beneath which seizure waves appear to start (epileptogenic

foci) have been described by Jasper and Hawke (*op. cit.*). Localizing signs were obtained in 13 out of 18 petit mal and in 20 out of 37 grand mal patients. They report also three cases in which seizure waves were picked up almost continually over a traumatic scar but not from other parts of the head. These patients were free from seizures at the time of examination. Since these waves were characteristically different from the seizure waves in other types of epilepsy, it was suggested that the form of the wave as well as its localization may be important in questions of surgical intervention. It is expected that the E. E. G. will add to the list of considerations cited by Penfield [17] as important in deciding on the surgical treatment of epilepsy, but we have not as yet had the opportunity to validate this application of the electroencephalogram. Localization is, of course, limited to those regions of the cortex lying subjacent to the head surface since only indirect gross indications can be obtained of deep lying foci.

Conditions Between Clinical Seizures.

Mental and emotional changes in some epileptic patients during the periods between seizures have long been recognized from clinical observation. It has been assumed that these characteristic changes, when they did occur, were in some way related to the pathological conditions which occasionally find paroxysmal overt expression or that they were sequelæ of the traumatic effects of the seizure itself. It has been difficult to explain, however, the apparent lack of correlation in many cases between the frequency and severity of the attacks and the more or less chronic personality changes or dementia noted between attacks. The E. E. G. provides a sensitive indicator of brain function during those periods when there is no clinical evidence of a convulsive state.

In epileptic dementia Berger [18] reports that 11 out of 14 cases showed large amplitude slow waves between attacks. Three cases having minor psychotic symptoms showed only occasional large slow waves in the E. E. G. In deteriorated epileptics Berger [19] found large amplitude slow waves (about 230 milliseconds, equivalent frequency 4-5 per second) which he contrasts with the *low* amplitude slow waves found in congenital idiots. Berger does not state whether the slow waves found in epileptic patients between

attacks resemble seizure waves or the irregular slow waves such as are found in other pathological conditions of the cortex.

In our own cases 11 out of 12 psychotic epileptics showed large amplitude slow waves between attacks. Some of these waves were of the spike and slow wave form but they were for the most part sudden large spikes, regularly repeated large smooth slow waves, or irregular disorganized rhythms. In all of these 11 cases there was almost continuous rhythmic activity of some type and the amplitude of the slow waves could be readily increased (3 to 10 times) by a short period (1-2 minutes) of hyperventilation even though a seizure was not produced. A certain amount of relatively normal record was also obtained. The ratio of normal activity as opposed to a pathological type was roughly proportional to the severity of the mental disturbance.

Pathological slow waves of large amplitude were also found between attacks in 13 deteriorated epileptics, corroborating Berger's findings with this type of case. We found that these patients were also very sensitive to hyperventilation which caused large, irregular potentials sometimes as high as 1000 microvolts after only one minute of hyperventilation. When these E. E. G. changes were present without a clinical seizure, mental confusion was often present.

In seven petit mal patients and in three grand mal patients who were quite free from any signs of intellectual deterioration or mental disorder, even though some were subjected to severe and frequent clinical outbursts in the overt seizure, the E. E. G. showed that they were relatively free from signs of sub-clinical epileptic disturbance between attacks. It is suggested therefore that the persistence of the pathological hyperactivity between attacks may be as important in determining intellectual deterioration and mental disorder as the frequency and severity of clinical seizures. The brain may be able to stand periodic paroxysms if allowed time to recover between attacks better than the continual bombardment by relatively less severe epileptiform activity. Furthermore, it is not surprizing that mental and emotional disturbances should characterize the epileptic personality between fits when we see the disorganized brain waves and momentary sub-clinical fits revealed in the E. E. G. of patients between overt seizures and even in some patients who have been free from overt seizures for many years.

The following case reports will illustrate the use of the E. E. G. in detection of inter-seizure epileptiform activity:

CASE 1.—A slightly built 7-year-old girl of pleasing appearance.

History.—Birth was normal at term with some complications due to a mild toxemia. Delivery was said to have been normal but the child was in poor condition for several days with cyanosis and frequent convulsions of the right side. From the age of 18 months she had grand mal convulsions most marked on the right side, occurring at intervals of from 1 to 5 months. Family and social histories are negative except that two paternal aunts are said to have had convulsions in childhood. There were a number of upper respiratory infections which seemed to be precipitating factors in some of her convulsions. Physical examination and laboratory studies were negative. Roentgen encephalographic studies showed no evidence of local or general atrophy. Since her treatment with phenobarbitol beginning in April 1935 (½ grain 3 times a day) she has been completely free from clinical attacks. Psychometric examination indicated an I. Q. of 105. School progress has been poor. Teachers report patient is "dreamy" and cannot concentrate.

E. E. G.—Examination after the patient had been free from any clinical attacks for 18 months showed almost continuous local seizure waves in the left precentral region. The record from other regions was essentially normal except that slow smooth potentials at 3 per second were very easily produced with only one minute of light hyperventilation.

CASE 2.—A well-developed girl of 11 years.

History.—The first convulsive attack was observed in July 1935. Five weeks later she had four generalized grand mal attacks in one day. Since then she has had frequent grand mal attacks usually occurring at night. She had been a very bright girl doing excellent work in school. More recently psychometric tests gave ratings on the same type of material at different times from I. Q. 86 to 109. During the period covered by these examinations she was having grand mal attacks at night three or four times a month. Her mental processes showed marked confusion, loss of memory, and lack of control, which were variable from day to day. Performance during psychological tests appeared to be arrested periodically by marked confusion.

E. E. G.—In records taken on a day during which the patient showed a more or less continuous state of confusion, large slow smooth potentials (300 to 400 uvs.) at a rate of about three a second were obtained, chiefly from the precentral and frontal regions with some occasionally from the occipital region (Fig. 2A). On one of her better days (when she showed less confusion and irritability) the E. E. G. showed lower amplitude potentials occurring regularly at about 7 per second (Fig. 2B). A brief period of hyperventilation produced a marked increase in the amplitude of the slow smooth rhythms with an occasional spike and slow wave form appearing, although no clinical seizure was induced.

FIG. 1.—Local and Generalized Seizure Waves in a Petit Mal Case. Sample A represents fairly normal brain potentials from bipolar leads to the left frontal (1), central (2), parietal (3), and occipital (4) head regions previous to an attack. Maximum amplitude of alpha waves is about 50 microvolts.

Sample B is taken from another portion of the same record during an attack with the same leads but reduced sensitivity. Note the synchronization of activity in all regions even though seizure waves differ in form. The maximum amplitude is seen in the occiput at about 500 microvolts.

Sample C was taken from a record on the same patient a week later at a time when she was irritable and periodically a little confused but did not lose consciousness. Simultaneous records from bipolar leads to the left frontal (1), central (2), and occipital (3) head regions are shown. At this time seizure waves appeared interspersed with normal alpha rhythm from the occipital region without spreading to other parts of the cortex. Calibration lines at the right indicate 50 microvolts.

FIG. 2.—Epileptoid Conditions Between Attacks (Case 2 in Text). The above record (A) was taken from monopolar leads to the right occipital (1) and to the right central (2) regions when the patient was showing marked confusion, irritability, and other epileptic personality changes. The record below (B) was taken with the same leads on this patient four days later when she was much brighter, better oriented, and less irritable. Calibration lines indicate 200 microvolts.

Epileptoid Conditions.

It is not easy to draw the line between pathological conditions which we might call genuinely epileptic from the clinical point of view and those states which appear to be less severe manifestations of the same type of disordered brain function. The following case reports will serve to illustrate, in children, the type of cases which are not usually diagnosed as epilepsy according to clinical criteria (loss of consciousness and convulsive movements) but which represent epileptoid conditions:

Case 3.—A 10-year-old boy of French Canadian parentage admitted as a behavior problem.

History.—For two years prior to admission the patient had been "nervous" and slept very poorly; there was an indefinite history of twitches and sleep walking. School progress had been poor and truancy a problem. Irritability and temper tantrums have been frequent. Patient complained of frontal headaches, sleeplessness, and nervousness. Mother was mentally deficient and had been subject to frequent grand mal seizures. Physical examination showed only somewhat sluggish reflexes and an undescended testicle. Psychometric examinations showed an average I. Q. of 80. No grand mal or petit mal attacks have been observed.

E. E. G.—Records were characterized by short bursts of large 3 to 4 per second smooth potentials more frequent in the frontal and precentral regions of the head. At times all regions would show 3 per second spiked potentials resembling very much those seen in a genuine petit mal attack although there was no apparent loss of consciousness or physical signs of convulsive activity.

Case 4.—A well-developed and well-nourished boy of 12 years admitted as a behavior problem.
